Congenital Syphilis of the Kidneys.—Dr. Roberto Massalongo, of Verona, reported a case of congenital renal syphilis in a child of eight months, who had also specific cutaneous lesions, resulting in death with uræmic symptoms. The renal arteries presented marked signs of endo- and peri-arteritis, and the same lesions were found in lesser degree in the liver and spleen; there was connective-tissue sclerosis of the kidneys. The histological changes found were similar to those seen in late renal syphilis (chronic interstitial nephritis) in distinction to those of precocious renal syphilis (parenchymatous nephritis, glomerulo-nephritis). Although in this case the lesions were of intrauterine development, the anatomical changes were those of the late adult form of renal syphilis. It must therefore be admitted that even in precocious syphilis of the kidneys the anatomical changes of interstitial nephritis may occur without a previous stage of the parenchymatous lesions. Syphilitic infection, at least the congenital variety, may primarily compromise in an acute manner the arterial system and produce in consequence dystrophic alterations in various organs. A micro-organism, as yet undiscovered, is without doubt the direct or indirect cause of the primary alteration of the arterial system. The syphilitic mother should be put upon an energetic course of treatment from the very beginning of pregnancy.

Gout and Uric Acid Concretions.—Dr. Mordhorst, of Wiesbaden, read a paper with the following conclusions: 1, The acids in the body oppose the destruction of the nitrogenous bodies, including uric acid; 2, the more alkaline are the body juices the more rapidly follows the destruction of the already formed uric acid and the less likely is the occurrence of uric acid deposits; 3, the deposition of uric acid depends especially upon the high acidity of the urine; 4, piperazine in daily doses of fifteen to forty-five grains has no appreciable solvent action on uric acid; 5, of all remedies bicarbonate of sodium is the only one that will satisfactorily reduce the alkalinity of the body juices without producing any harmful by-effects; 6, those mineral waters which contain the greatest proportion of bicarbonate and chloride of sodium and the least of lime salts are the best for use in gout; 7, the best of these is the Wiesbaden "gout-water;" 8, only neutral and alkaline urine, not clouded by lime phosphate, is capable of preventing the formation of uric acid concretions, or of dissolving those already formed; 9, the Wiesbaden "gout-water," so poor in lime salts, alone can produce such an alkaline crystal-free urine; 9, in the treatment of these cases a suitable diet, as free as possible from meat and alcoholic drinks, is indicated; 10, the prevention of gouty deposits is obtained for the most part by muscular exercise, warm clothing, mineral baths, cold frictions, massage, and electricity.

Cold as an Etiological Factor in Chlorosis.—Dr. Augusto Murri, of Bologna, said there was a winter form of chlorosis due to the action of cold. In cases in which chlorosis already exists, intense and prolonged cold applied to the cutaneous surface induces hemolysis, but this action is also observed occasionally in healthy individuals. The mechanism of this hemolysis is probably to be found in modifications of the vaso-motor nerve conditions. The treatment of winter chlorosis consists in hydrotherapy and in long confinement of the patient in bed.

The Action of Diphtheritic Poison on the Blood.—Dr. Giuseppe Mva, of Florence, said that diphtheritic infection always caused a greater degree of hemocitosis (as was first remarked by Bouchut), but that this affects in no way the prognosis of the disease. On the other hand, the diphtheritic poison exerts no strong deleterious action on the red blood globules or on the hemoglobine. With this fact stand in close relation the renal lesions, so often observed in the course of diphtheria.

Subacute Poliorromenitis.—Dr. I. Monteverdi, of Cremona, read a paper with this title. The affection observed in his patients resembled clinically the disease called by Concato scrofulous poliorromenitis, or phthisis of the serous membranes. Its unvarying symptomatology showed that it was independent of other infective processes or of visceral diseases, and constituted a nosological entity. The tuberculous nature of the disease, regarded as probable by Concato and Picchini, was confirmed by autopsy in some of the author's cases. The following conclusions were formulated by Dr. Monteverdi as the result of his observations: People living in country districts. Heredity has very little influence. Intestinal disturbances, typhoid fever, scrofulous affections, and amenorrhœa are the most common of the predisposing causes; those affected are usually in a depressed general condition. The disease not infrequently occurs as a sequela of influenza. Its onset is usually subacute without any definite prodromic period, one serous membrane being first attacked, usually the peritoneum, the others

being invaded secondarily. The fully established disease ordinarily involves the peritoneum and both pleural sacs, the pericardium frequently escaping. The peritoneal form is usually accompanied by serous exudation, but the pleurisy is more commonly dry, and seldom, if ever, serous on both sides. Pericarditis is very rare, and endocarditis has never yet been observed. The serous membranes of the joints are occasionally attacked, but the meninges are always spared. In severe and fatal cases there is often hypertrophy of the heart.

The pulse is generally weak but regular, and almost always frequent, especially at the beginning of the disease. The liver and spleen are usually normal, being only exceptionally enlarged. At first the urine is scanty, but it becomes normal in quantity later, especially if the disease assumes a favorable course. It is usually turbid, throwing down a copious deposit, its reaction is acid, specific gravity 1010 to 1039, is sometimes albuminous, and may contain chlorides, phosphates, urates, carbonates, and uroindican, but never sugar.

In some cases tuberculous utero ovaritis is found at autopsy, and in one instance the presence of a salpingo-oöphoritis of the left side with anteflexion of the uterus was made out during life.

The fever is usually of the quotidian intermittent type, with exacerbation between four and six o'clock in the evening, less frequently remittent.

The termination of the disease is usually favorable when the fever is not high. The elevation of temperature occurs for the most part without a previous chill, and subsides, especially in mild cases, with moderate sweating. The duration of the disease was from two to twenty-six months in the cases observed by the author, being in half the cases less than seven, usually between two and six.

The treatment of poliorromenitis is rather medical than surgical, and is based on anti-microbic lines. Care must be taken also to increase the secretions by means of diuretics, purgatives, and sudorifics, in order to favor the absorption of the exudates, and combined with this is the symptomatic treatment, varying in special cases according to the indications.

Hysterical Fever.—Dr. Giacomo Lumbroso, of Livorno, reported a case of hysterical hyperpyrexia occurring after influenza, in which the temperature ran at times as high as 113° F., the type of the fever being usually remittent, though for a while it was continued. Repeated examinations showed that the elevated temperature existed in certain regions only, which regions were also often hyperæsthetic. He attributed the phenomena to functional lesions of the thermic centres.

Vetch Poisoning.—Dr. Giovanni Montano, of Lavello, Italy, described a disease produced by the common Italian bean, *vicia faba*, characterized by an icteric discoloration of the skin, disturbances of the nervous system and of the abdominal organs, and the passage of bloody urine, but without fever. The affection attacks individuals having a special idiosyncrasy, often hereditary, in regard to this vegetable or the odor of its flowers. Physical misery, mental troubles, cold, alcoholism, syphilis, and malaria are not to be reckoned among the predisposing causes. For predisposed persons to acquire the disease, it is not at all necessary that they should have made a quasi-exclusive diet of these beans, that the beans should be spoiled, or that the individuals should have inhaled the odor of the flowers for any length of time; they need only have eaten a few sound beans or taken a mere whiff of the odor of the flowers in order to be attacked with "favismus," as the author designates the affection. The pathogenesis of the disease is probably to be referred to a blood-poisoning which causes immediate and exaggerated hemolysis, hemoglobæmia, biliary pleiocromia, and hemoglobinuria. The course, duration, and result of the disease vary according to the intensity of the cause and the predisposition of the individual. In mild cases and those occurring in young persons, castor-oil, lemon-juice, black coffee, and cold applications to the epigastrium are of service, but in very severe cases nothing can avert the fatal issue.

Strumectomy in Basedow's Diseases.—Dr. Mikulicz, of Breslau, presented a communication with this title, in which it was held that extirpation of the thyroid was indicated in all cases of Basedow's disease in which even the slightest signs of tracheal stenosis are present. How far the operation is indicated in other cases where no such symptom exists must be determined by further experience. All operative procedures which cause a diminution in size of the thyroid gland, even the simple ligature of the arteries supplying it, may bring about an improvement in the symptoms or even effect their disappearance. Some cases of Basedow's disease are entirely cured by the operation, but how this cure is brought about is not very clear as yet; it may possibly be in one of three ways, viz., a diminution of the functional activity of the gland substance; a relief of the stretching and irritation of the sympathetic nerve fibres; or, finally, in the removal of pressure, however slight it may be, from the trachea.

Chylothorax.—Dr. Giuseppe Mya, of Florence, reported a case of chylous effusion into the right pleural cavity, the second or third clear instance of this disease which he had found in medical literature. He exhibited some of the fluid removed from the chest, and gave the analysis which he had made of it.

Observations on the Function and Pathology of the Heart.—Dr. Luis Ortega Morejon, of Madrid, presented a communication with this title, in which he held that the auricular appendages serve primarily as balances of compensation for the auricles, and also to mix the venous blood with the chyle on the right side and to oxidize the plasma on the left.

Cerebral Echinococcus.—Drs. Mya and Codivilla, of Florence, reported a case (with presentation of the patient) of echinococcus cyst in the centrum ovale in a man twenty-four years of age. The diagnosis was made from the symptoms presented by the patient, and an operation was performed resulting in a perfect cure.

Bovine Tuberculosis.—Dr. Nocard, of Belfort, said that bovine tuberculosis was on the increase in Europe, and the sole cause of this increase was contagion, heredity and other alleged etiological factors being of relatively insignificant importance. Contagion, however, acts only when healthy animals remain for a long time in close intimacy with the diseased, hence isolation of those affected with the disease would suffice to put an end to the spread of the affection. The clinical diagnosis has been so difficult hitherto that it was almost impossible to realize this much-to-be desired result; now, however, nothing is more easy, for an injection of tuberculine suffices to render the disease evident even when the lesions are almost infinitesimal. From this we may deduce a method of prophylaxis at the same time simple, cheap, and efficacious, to wit: All the animals in an infected locality should be submitted to the tuberculine test, those recognized as diseased being removed and slaughtered; then the stable of the healthy animals being thoroughly disinfected, no new animals should be admitted to it until they have been shown by the tuberculine test to be sound.

Al Nauchah.—Dr. Hassan Pasha Mahmoud, of Cairo, Egypt, read a paper on al nauchah, which is, he said, a form of continued fever not hitherto described. It occurs in Egypt at all seasons, but chiefly in spring and summer. Three stages are usually well defined, namely, of invasion, of increase, and of decline. The duration of the disease is about three weeks. It is very regular in its course, and its convalescence is less prolonged than that of typhoid fever, relapses during this period being, however, quite common. Once the patient has fully recovered, a second attack does not occur. The treatment is rather symptomatic than specific, special regulation of the diet being absolutely necessary.

Pleuritic and Malarial Fevers.—Dr. Luigi Marescotti, of Rignano Flaminio, Italy, presented a communi-

cation in which he said that pleuritic fever, by reason of its intermittent character, was often popularly mistaken for malarial fever, and hence improperly treated. By the time that the disease becomes so serious that the patients seek medical advice, it is generally found that it is tuberculous in character. The author had met with many such cases in his practice in the Roman Campagna during the past two years.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 27, 1893.

H. P. Loomis, M.D., President, in the Chair.

Microcephalic Idiocy with Epilepsy and Blindness.—Dr. Frederick Peterson presented the fresh brain from a case of this kind. The patient was a female, twenty-eight years of age, and was from birth an idiot with epilepsy and some left hemiplegia, belonging therefore to the class of congenital spastic hemiplegias. She averaged one epileptic attack daily until three days before death, when she went into the *status epilepticus* and had seizures about every four minutes, general in character, though sometimes left-sided. Though she could distinguish light she could not find her way about, and had all her life to be cared for like a child. At the autopsy, the skull was found to be microcephalic to some degree. The bones were thickened, and the sutures closely united. The dura was normal, as was also the pia. Both occipital lobes were the seat of great atrophy and sclerosis, the loss of tissue being made up for by widely dilated posterior horns in the ventricles. The cerebellum projected far beyond the posterior lobes; the anterior lobes were small and narrow, and the atrophy and sclerosis extended partly into the motor area on the right side.

Extensive Typhoid Ulceration.—Dr. George P. Biggs presented the intestine from a case of typhoid fever. It was interesting on account of the extensive lesions of the cæcum and ascending colon. The case presented the ordinary clinical history of typhoid fever and had progressed to the fourth week, the temperature remaining quite high for most of the time. She did quite well up to about twenty-four hours before death, when she complained of abdominal distention and pain. The autopsy showed acute general peritonitis of short duration; no perforation had occurred. There were the usual lesions in the spleen and mesenteric glands, and also in the lower three feet of the small intestine, but from the cæcum up nearly to the hepatic flexure of the ascending colon the ulcers were very large and deep, and were so numerous that almost half of the mucous membrane had been destroyed. The ulcers were very deep, and the one which caused the peritonitis was located on the anterior wall of the cæcum at about the level of the ileo-cæcal valve. Here the ulceration had extended down to the peritoneum. Perforation had not occurred, but on lifting the intestine slight compression was made at this point, and this was sufficient to produce perforation.

The speaker said that the ulcers in the large intestine in cases of typhoid fever were quite common; in fact it had been his experience that an entire absence of them here was the exception rather than the rule. In this case all of the large intestine was involved, one ulcer being found as low down as the rectum, but the ulcers beyond the ascending colon were few.

Dr. S. T. Armstrong said it had not been his experience that ulcers of the colon were frequent in typhoid fever, or that the ulceration was so extensive as in this specimen. He thought it possible that this might have been a case of ulcerative ileo-colitis, in which case the symptoms would probably closely resemble those of typhoid fever.

The President said he would consider the ulcers in the specimen to be characteristic of typhoid fever: the size, the floor of the ulcer, and the clean cut edges should distinguish the typhoid ulcer from the ragged-edged dysenteric ulcer.

Dr. F. Tilden Brown said that about ten days ago, at the Presbyterian Hospital, he had been present at an autopsy on a case of typhoid fever, and there was even more extensive ulceration, very large ulcers being found in the upper part of the rectum. The patient had had several severe hemorrhages, and although a number of the ulcers were exceedingly deep, there had been no perforation.

Dr. Biggs said that in the cases of ileo-colitis which he could recall the mucous membrane, as a whole, showed inflammatory change, and there were comparatively few ulcers of Peyer's patches, and of the solitary follicles. He had noticed these ulcers of the colon especially in the cases of typhoid fever which he had seen this year.

Dr. Armstrong said that in the course of his reading he had seen it stated somewhere that cases of typhoid fever treated by cold baths exhibited unusually extensive ulceration. He would, therefore, like to know whether this accorded with the experience of Dr. Biggs.

Dr. Biggs replied that most of the cases he had seen had had the cold-bath treatment, but he had never before had his attention called to the fact that in such cases the ulceration was more extensive.

Cystic Chylangioma.—Dr. Biggs then presented a specimen of an abdominal tumor removed from a girl seven years of age, who had been suffering with symptoms of intestinal obstruction for eighteen days. The tumor was a lobulated cystic mass measuring $9 \times 6 \times 3$ ctm. One surface was covered by normal peritoneum, while the other was roughened and showed the lines of incision made in its removal. The cyst cavities communicated more or less freely with each other, and were partially collapsed as the result of aspiration of the largest one, and the cutting of many small ones during the excision of the tumor. They varied in size from pin-points to the largest, which were 5 ctm. in diameter, and were held together by adipose tissue. In the natural state, before aspiration, the tumor must have been nearly three times its present size.

Microscopical examination of the whitish fluid from the cysts showed only a few leucocytes and much granular matter. Sections of the more solid portions of the tumor showed irregular spaces, probably dilated chyle vessels, containing granular matter, and more or less completely lined with elongated, flattened cells. Between these spaces was adipose tissue, a few areas of small round cells, and a few small lymphatic glands. The tumor, therefore, was a "cystic chylangioma," probably congenital in origin, which did not cause symptoms until it had attained sufficient size to produce intestinal obstruction.

The speaker said he was indebted to Dr. O. O. Cooper, of Hinton, W. Va., for the specimen, which was accompanied by the following history:

Two years previous to her last sickness, the child had an attack of severe pain all over the abdomen, with vomiting and intestinal obstruction, lasting four or five days. After this she would often stop suddenly, while playing, and complain of severe abdominal pain. When Dr. Cooper was called in consultation he learned that she had suffered constant severe abdominal pain for eighteen days, during which time nothing had been passed by rectum, and the stomach had refused to retain food, the vomited matter being fecal on several occasions. Life had been maintained by the use of nutritive enemata. She was extremely emaciated, had an anxious expression, and her abdomen was so tender it could not be touched. Her temperature was normal, pulse 110 and very feeble. She absolutely refused to take nourishment by mouth because of the vomiting which was sure to follow.

Operation was strongly advised as holding out the only possible chance of recovery, intussusception or volvulus being suspected. Upon opening the abdomen, the whole intestinal tract was found much congested, almost of a mahogany color. An irregular, lobulated, cream-colored tumor, nearly as large as a child's head was found attached to the lower end of the ileum for eight inches. It looked like fat, but was elastic and fluctuating. A trocar was

introduced into the largest lobe, and about five ounces of chylous-looking fluid escaped, leaving the whole mass flabby. Some hesitation was felt about undertaking the removal of the tumor, but as it was rather easily stripped from the gut, excision was finally decided upon. Many ligatures were used, and the wound was packed with gauze. During the operation the patient passed a quart or more of fæces. She rallied well, said she felt better than she had in weeks, and took and retained milk and whiskey by mouth. The improvement was only temporary, however, and she died the following day. No autopsy was obtained.

A few of these chylous tumors of the intestinal canal, originating in the mesentery as in this case, have been described; they are made up of enormously dilated chyle-vessels. They are of congenital origin, but as they grow they give rise to symptoms, usually earlier than in this case.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Special Meeting, February 27, 1894.

CHARLES A. POWERS, M.D., CHAIRMAN.

Compound Fracture of the Oleeranon Process Treated by Secondary Suture.—DR. H. LILIENTHAL presented a young man who, about a year before, had fallen against a buzz-saw and cut the elbow. The limb was dressed at Bellevue Hospital in the extended position. Two weeks afterward he fell and broke the splint, and reopened the wound. At Mount Sinai Hospital compound fracture of the elbow was diagnosed, a splint was put on, the wound apparently healed; but when the splint was taken off the wound broke out again and the compound fracture was again present. On July 17th Dr. Lilienthal wired the broken olecranon to the main bone, and the result had been so good that the patient had regained perfect use of the limb.

Partial Excision of Hyoid Bone for Fistula.—DR. CARL BECK presented a woman, aged forty-five, with a congenital fistula of the neck leading to the hyoid bone; it had closed and reopened from time to time. She suffered from dryness in the back part of the tongue, pain, and some hoarseness. Such cases were rather rare, and as the symptoms were usually unimportant, the patients seldom visited the surgeon. He had usually closed the fistula by introducing the galvano-cautery wire, but it failed in this case, as did also excision of the lining membrane. Finally, on opening up the tract, he found it led to a small cavity on the other side of the hyoid bone, and after removing the right half of this, together with the fibrous lining of the little cavity, and closing with suture, the cure was complete. Curiously enough, the patient had not had since the operation the slightest difficulty with deglutition or speech, and the hoarseness and dryness had disappeared.

Inguinal Hernia Cured by Bassini's Operation.—DR. W. B. COLEY presented about twenty boys and men in illustration of the cure of inguinal hernia by Bassini's method. During the past two years and a half he had thus operated upon 86 cases, 24 adults and 62 children. No mortality. Thus far but one relapse, and this occurred in a case in which he used silk sutures, attended by suppuration, the technique being responsible for the failure, not the operation itself. Later he had used only kangaroo tendon, for both deep sutures and in the aponeurotic layer, closing the skin with catgut. He never used drainage. Since adopting this rule he had had 22 cases with primary union in adults, 46 in children. On one of the boys presented he had first done Cherney's operation about two years ago, and in spite of the fact that he wore a truss there was recurrence. Thereupon he performed Bassini's operation, no truss was applied, and there had not been a relapse, now a year and a half. One patient was a man who had a hernia which could not be controlled by truss, yet since the operation, without a truss, he had pursued his occupation, lifting heavy machinery.

It was generally supposed that we must wait over two years to judge of the probable permanency of cure of hernia by operation, but an analysis of the cases of relapse appearing at the Hospital for the Ruptured and Crippled, cases operated upon in all parts of the country by various operators, but mostly by the best New York surgeons, showed that in 171 of non-strangulated hernia, the relapse had occurred during the first six months in about seventy per cent., and during the first year in about eighty six per cent. Of the remaining fourteen per cent. the relapse took place in five per cent. during the second year, the remainder, or eight per cent., later. During the same period, the past five years, 79 cases had appeared in which there had been strangulated hernia, and these gave about the same percentages as the non-strangulated. Therefore, as most of his own cases had been operated upon over a year, they could be considered cured.

Compound Fracture at the Elbow.—DR. F. KAMMERER presented a boy who had come under his care last May, with compound fracture just above the elbow-joint. He dressed the wound, put the limb up in the extended position; the external wound healed kindly, but after three months it was found the bones had not united, so that he cut down and, after encountering much difficulty, succeeded in freshening the surfaces and uniting the fragments with silver wire. The wire was removed three weeks later, but the bone was kept extended and immobilized six months; then, three weeks after commencing passive and active motion, the result was perfect; motion was normal in all directions.

Venous Angioma of the Hand.—Dr. Kammerer exhibited a man showing the results of an operation for venous angioma of the hand. The tumor had existed thirty-five years, had enlarged, was chiefly on the dorsum, increased in size when the hand was dependent. It did not pulsate. Five weeks ago he made a longitudinal incision over the tumor and excised it, meeting with some difficulty as it extended beneath the extensor tendons and the wrist ligaments, so that at the close of the operation the tendons were bare and some were without the sheath. Healing was allowed to take place under moist blood-clot, and the result had been remarkably satisfactory, better, he said, than could have been obtained by any other method.

Discussion having been called for, DR. LILIENTHAL thought silk could be sterilized in hernia cases at the time of the operation, so that it would not cause suppuration. He used it just out of a boiling solution. DR. KAMMERER and DR. B. F. CURTIS had also had no special trouble with silk.

DR. COLEY replied that it was not a question whether it was possible to sterilize silk so that suppuration would not take place, but rather whether, with the usual care devoted thereto, it did not more or less frequently cause suppuration. Billroth's results and others', showed that this material was much more likely to be attended with suppuration than was kangaroo tendon, as demonstrated by his own cases. Dr. De Garmo had told him that he had given up silk because he had had a number of cases of suppuration. Kangaroo tendon possessed the advantage that it held long enough and finally was absorbed.

The Radical Cure of Hernia by a New Method.—DR. A. M. PHELPS presented a patient and illustrated by drawings a new method for the radical cure of hernia. Relapse in oblique hernia took place at the internal ring, and no matter how strong the walls outside, if the internal ring had not been fortified, relapse was quite likely to take place. To this end he had proposed a method which deviated somewhat from trodden paths. A long incision was made, extending at least two inches beyond the internal ring through the muscles, the sac was opened, the intestine replaced. In a thin sac the suture should be passed with a needle around the neck, and half of the sac, or a little more, cut away, the stump in-

verted with the forceps into the abdominal cavity, and the ligature tightened. This secured the stump within the cavity. A single stitch or two across the neck of the sac was then necessary. The muscles should be dissected up from the transversalis fascia a distance of an inch and a half, either way, from the internal ring. The internal ring being a hole in the transversalis fascia, it should be closed, and to do this its edges were denuded, then, half an inch to an inch on either side of the ring, two parallel longitudinal incisions were made, after which it was easy to bring the fasciæ together over the stump, interrupted silk sutures being used. Over this fascia he placed loops of silver wire or catgut; four to five, two to three inches in length, would suffice. They were passed underneath the cord from the internal to the external abdominal ring. Over the loops the transversalis muscle was carefully stitched with interrupted sutures, the cord being brought through the muscle direct. The first layer of wire ran transverse to the inguinal canal. Over the transversalis muscle another layer of wire loops was passed, at right angles with the former. Each loop was stitched to the muscle to prevent slipping. Over the second layer of wire the internal oblique was stitched with interrupted sutures. The external oblique was stitched together. If there was a thick layer of superficial fat the wound was dressed open, otherwise closed. A small drainage tube was inserted down into the sac when the sac had been inverted into the abdominal cavity; but when the sac was cut away a few strands of catgut passing to the deeper layers of muscle would suffice for drainage. Dress at the end of the third day. Thus far he had seen no suppuration. His cases were too recent to speak of permanent cure.

Where the sac was large and thick, he utilized the mass as a pad placed against the internal parietes to prevent recurrence of the hernia. Its peritoneal surface was freely scarified, in order that adhesions might quickly form between it and the abdominal peritoneum. It was drawn in by a catgut suture which was brought out at a small opening made for that purpose above the ring, and fastened. The incision into the sac should always be closed by catgut sutures before introduction into the abdominal cavity. The mouth of the sac should be stitched together with one or two interrupted sutures, not sufficient to cut off the circulation of the sac. A drainage-tube was inserted into the sac for two or three days.

The operation described by Dr. Phelps was criticised by Drs. Bryant, B. F. Curtis, Kammerer, Coley, and others. They thought the presumptive advantages were not real, and that the technique was attended by dangers not incident to other approved methods. Dr. Manley meant to give the procedure a trial, believing that no method yet proposed for the radical cure of hernia was perfect. Dr. Dawbarn mentioned his method of occluding the inguinal canal by making use of the testicle, described in Wood's "Handbook of the Medical Sciences."

A Method of Differential Diagnosis in Œsophageal Stricture.—Dr. H. Lilienthal reported a case of œsophageal stricture in a man in which it was a question whether there was regurgitation of fluids from the stomach or from an œsophageal diverticulum or dilatation. The regurgitation took place whenever the patient stooped forward. The plan adopted was to pass a tube through the stricture into the stomach, introduce a colored fluid, then allow the patient to swallow some clear water. Then on bending forward the fluid regurgitated was clear, showing that it came from a diverticulum, not from the stomach. The method had also been successful in another case.

Dr. Torek said he had reported a case in a German paper in which he was able to say that the obstruction to the œsophagus was pressure by an aortic aneurism, from the fact that its pulsations were transmitted to a tube introduced into the stricture.

Intussusception of the Ileum Produced by Bicarbonate of Sodium; Demonstration on a Rabbit.—Dr. R. T. Morris exposed the ileum of a rabbit, placed a bit of bicarbonate of sodium upon its surface, whereupon it was observed to undergo intussusception. The circular fibres first contracted, narrowing the gut, then the longitudinal fibres contracted and drew the narrowed portion into the adjoining part. Chloride of sodium did not have this effect, and could be used to produce reverse peristalsis in determining the direction of the gut.

Stated Meeting, April 5, 1894.

D. B. St. John Roosa, M.D., President, in the Chair.

The Library.—Dr. Egbert H. Grandin, chairman of the Committee on Library, read the names of a number of donors of books since the last meeting, announced that there would be a sale of triplet volumes to private parties during the present month, and gave notice of a proposed amendment to the by-laws, permitting Fellows to take books and journals to their homes for a period of two weeks. Later the President requested Dr. Grandin to make a statement as to the work which the Committee on Library proposed to carry out during the summer, which he did, and concluded by expressing the hope that some of our wealthy citizens who wished to donate five hundred thousand dollars to some worthy purpose would remember the library of the Academy.

A Valuable Painting.—The President called attention to a valuable painting donated by some members of the Academy, representing Ambrose Paré on the field of battle, making the first ligation of a wounded artery, in the presence of the King of France, it being a copy by the author himself of his original picture in the School of Medicine.

Membership Invited.—The President called attention to the advantages of membership in the Academy, and hoped the Fellows would propose the names of those of their acquaintances known to be qualified by three years' practice worthy of the honor.

Some Recent Measures in the Treatment of Epilepsy, with Special Reference to the Use of Opium; the Reader's Experience with Fleschig's Plan.—Dr. Joseph Collins read the paper. Among remedies which had been recommended within the last few years were borax, antipyrine, antifebrine, various bromides, nitroglycerine, antirabic inoculations, hypodermic injections of cerebral extract, duboisin, cannabis indica, opium, etc. Dr. Collins approved of a wholesome scepticism in approaching new remedies for epilepsy. Many had been tried, highly recommended for a time, then had fallen into disuse. He knew of nothing yet discovered which at all approached bromide of potassium in value. About a year ago Flechsig, of Leipsic, published an article, giving satisfactory results from the administration of large doses of opium for a period of six weeks, followed by good doses of bromide of potassium. In view of the reasonableness of the method and its introduction by so high authority, Dr. Collins decided to give it a trial, and through the kindness of Dr. Dana, Dr. Fisher, and others he had been able to apply it in fifty cases, a small number having been seen in private practice. The dose of the opium was started at one grain, the daily amount was rapidly increased to fifteen grains or more. At the end of six weeks the opium was suddenly dropped, and the patient was put on half-drachm doses of bromide of potash, repeated four times a day, and after this had been continued awhile the quantity was gradually decreased to about forty grains a day.

Most of the cases treated were old ones on Blackwell's Island, of the *haut mal* type, with some mental deterioration. The conclusions reached were: the plan suggested by Flechsig was not a specific; all the cases except one were benefited; the fits stopped for a time; relapse generally occurred in a period varying from a few weeks to a few months; the frequency of the fits for the first year after the treatment was lessened at least one-half; attacks occurring after relapse were much less severe in character;

the plan was particularly valuable in ancient and intractable cases; in recent cases of idiopathic epilepsy it could not be recommended; the opium plan was a valuable adjuvant to the bromide plan as ordinarily applied; the opium acted symptomatically, and merely prepared the way for, and enhanced the activity of, the bromides.

Dr. E. D. Fisher, who arrived after the reader had concluded, said the cases treated by Dr. Collins which had been seen by him were benefited by the method, but he had very grave doubts whether any cases could thus be cured. The plan seemed best adapted to chronic cases. While he had not seen danger from the use of the opium, the stupid state of some of the patients seemed somewhat greater; at least the attendants had found them more tractable.

Dr. Frederick Peterson thought that in chronic cases of epilepsy where ordinary treatment failed Flechsig's plan was undoubtedly useful.

Fears the Opium Habit.—Dr. W. H. Thomson argued that epilepsy was an organic disease, whose distinguishing symptom was suddenness of attacks of the nature of a convulsion, loss of consciousness, or fainting, etc. An organic disease could not be cured by a functional medicine, such as the nervines, to which class opium belonged. As an adjuvant to the bromides, which when used properly constituted our most reliable agents, he preferred chloral, and especially antipyrine, to opium. A weighty objection to the opium plan was the danger that the patient might take on the opium habit as soon as he passed from under the surveillance of the physician. He ventured to say that Flechsig himself would abandon the treatment after a year or two.

Dr. Collins had noticed no deleterious effects from the opium method, and he had seen no tendency to the formation of the opium habit. Two patients had become maniacal, but while on the bromides and after an interval following cessation of the opium sufficiently long to convince him the opium had had nothing to do with it. Regarding opium being only a functional medicine, causing no anatomical changes which could be discovered, this was equally true of epilepsy, although it was at present generally regarded as an organic disease. Besides, opium caused cerebral congestion, while epilepsy was followed by cerebral anæmia, and it seemed reasonable that by keeping up the circulation in the brain with opium the epileptogenous discharge could be obviated, which had been done by this treatment. Nor was it unreasonable to suppose that a functional medicine which maintained a physiological state during its use might not end in cure of an organic disease. He had not claimed, however, more than a valuable adjuvant to the bromides in Flechsig's plan.

The President remarked with feigned surprise that he had heard during the discussion no reference to the treatment of epilepsy by cutting the muscles of the eyes, from which he would infer that this method had little standing among neurologists.

Appendicitis Strictly a Surgical Disease.—Dr. John A. Wyeth read a paper in which he related cases in support of the belief that appendicitis should always be regarded as a surgical disease. Numerous papers relating to the general subject of appendicitis had appeared in recent medical literature. The danger to life which made appendicitis strictly a surgical disease was peritonitis, and this might occur with or without perforation. Septic germs or ptomaïnes might escape where there was disease short of perforation and precipitate peritonitis. Fecal odor in the peritoneal cavity where no perforation existed was now and then encountered. In the whole range of materia medica there was no remedy which would cure appendicitis and prevent infection therefrom. The physician was powerless, save in allaying pain and rendering the patient comfortable. The author had not seen a single death from the affection which could not properly have been ascribed to delayed skilful interference. With all respect to the diagnostician, he did not believe it was possible to determine by symptoms whether perforation was or was not about to occur. This did not imply that by a study of symptoms one could not make out perforation in a good proportion of cases when this had occurred.

The death-rate from appendical operations at present was eighteen per cent. It ought easily to be brought down to five per cent. by avoiding unnecessary delay, and if all cases were operated upon within the first twenty-four hours by skilful surgeons it would be reduced to one or two per cent. The surgeon might be mistaken now and then and operate where it was not necessary, but the error would be on the side of safety. Opening into the peritoneal cavity was not a dangerous procedure, and the likelihood of hernia occurring at a small incision was slight. In none of Dr. Wyeth's cases had hernia developed. The operation was one which the inexperienced should avoid.

Medical Testimony.—Dr. Simon Baruch related his experience with appendicitis, beginning at about 1880. For the next four years, surgical treatment having been rejected by himself and some of the consultants, the patients died. He then made up his mind that surgery alone offered any hope; that the inflamed appendix, like a bullet, was a foreign body which should be removed. About the first case on record of cure of perforative appendicitis by operation was one in which he called Dr. Sands in consultation. A similar case with successful result had been operated upon for him by Dr. Wyeth. Dr. Baruch advised against giving morphine, as it would obscure the symptoms.

Dr. Dessau, while recognizing the fact that the diagnosis might sometimes be in doubt, and also that some cases of apparently straightforward appendicitis had recovered permanently without operation, was disposed to agree with the author that a surgeon should be called in consultation at the beginning.

Salicylate of Soda in Appendicitis. — Dr. Lesser thought that, since appendicitis had come to attract so much attention on the part of the laity as well as physicians, a great many cases of entero-colitis were mistaken for this affection. The patient's fears were enhanced by the fact that pressure over the region of the appendix in both conditions caused pain. Opium not only obscured the diagnosis, but did actual harm by checking secretions and increasing tympanites. Salicylate of soda increased the secretions, reduced tympanites, relieved pain, and sometimes checked inflammation before the occurrence of gangrene or suppuration, whether in appendicitis, salpingitis, or other pelvic inflammations. It was not unreasonable to suppose that catarrhal appendicitis could be relieved without an operation as well as catarrhal salpingitis. He gave the salicylate of soda in gramme doses every two hours.

Dr. Robert T. Morris said: "This whole question is easily reduced to its principles. Appendicitis is an infective exudative inflammation caused by bacterial invasion of the tissues of the appendix, and persisting after subsidence of acute symptoms. Appendicitis is not at any stage a medical disease, for the reason that the bacteria which cause the infection are not killed by medical resources, although acute symptoms may be made to disappear. Surgery removes the nest of bacteria. The earlier an operation is done the greater the credit to rational practice. A surgical death-rate of one per cent. in appendicitis is a death-rate of inexperience—inexperience on the part of patient, physician, or surgeon. A hernia-rate of one per cent. after the operation is a hernia-rate of inexperience. Death, hernia, and suffering are preventable in appendicitis cases.

"The inch-and-a-half abdominal incision which I employ keeps the patient in bed eight days. He leaves his room on the tenth day. This is practical only after the employment of a technique which unites each cut structure accurately and separately with fine catgut. It is not adapted to pus cases. Curiously enough some surgeons have reasoned that I had easy cases to deal with because of the results of this technique. That is not

true. I have no voice in the selection of cases; these patients are all sent to me by their family physicians, who send cases that they believe to be in need of operation —many of them after desperate complications. There is no theoretical feature about this technique that I employ. It is a practical, every-day routine work in which I am engaged. Appendicitis cases cannot be medical cases because of their nature, but I depend upon the general practitioner to manage the cases apart from my special work, and should feel very uncomfortable were I to be deprived of his counsel and aid. I do not come across any cases of catarrhal appendicitis."

Dr. Wyeth, in closing, expressed the opinion that salicylate of soda would prove powerless where there was a septic process affecting the peritoneum, and he was afraid that, like other remedies, resort to it would simply lead to delay in calling a surgeon and thus keep up the mortality rate. One should not take the risk of removing the appendix through an inch and-a-half incision. Working in the dark, he might cause perforation or break the walls of an abscess and infect the general peritoneum. It was much better to make an opening large enough to see what one was doing, and to introduce gauze and shut off the diseased area. There was little danger of hernia. In none of his cases had hernia developed. The patient should remain in bed six weeks.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, March 26, 1894.

Seneca D. Powell, M.D., President, in the Chair.

Advertising and the By-Laws.—The President said that he had been requested by the comitia minora to call attention to the by-law which forbade advertising, fixing one's name to nostrums or proprietary articles, etc. Complaints had been received which would have the attention of the Committee on Ethics.

Brief Note on Some Cases Recently Admitted to the Surgical Service of the New York Cancer Hospital.—Dr. Charles A. Powers read the paper. The cases entering the Cancer Hospital were classified as operable surgical cases, operable gynecological cases, and inoperable cases. The paper had to do with the operable surgical cases, of which there had been over twenty the past month or two, exclusive of non-malignant tumors. Cancer of the breast was much the more common—eight operable cases, four inoperable. In one of operation on the lower jaw, there had been death from septicæmia.

A surgical division of the cases was into those in which it was thought the disease could be thoroughly excised, and the patient would have a fair prospect of cure; cases in which the surgeon was in doubt whether he could go beyond the limit of the disease; finally, cases which were frankly incurable, but in which a palliative operation would afford a fair chance of prolonging life and adding to the patient's comfort. Examples of the three classes were given. Of the second class the case of Mrs. H—— was related, who fifteen months before had noticed a little hardening in the upper quadrant of the right breast. A physician called it large milk veins. It slowly increased. Dr. Powers found a mass as large as a mandarin orange; skin movable; nothing felt in the axilla. Excision of the breast and axillary glands in February. Microscopical examination showed the mass to be carcinoma. The prognosis was dubious, because one could not be assured but what some diseased glands remained. An example of the third class was that of a patient who had a mass of evidently cancerous tissue involving the breast, with adhesion to the chest-wall, the overlying skin red and adherent, the nipple retracted, a mass the size of a pigeon's egg in the axilla. He removed the breast and axillary fascia, but even after an extensive dissection it was observed that not all diseased tissue had been removed, so that recurrence seemed certain. Eighty-one per cent. of the cases belonged to the third class, only nineteen per cent. giving any prospect whatever of radical removal and cure. The lesson taught was not new, that if we would cure cancer we must attack it very early, while the disease was yet essentially local.

The Management of Incurable Cases of Cancer.—Dr. Daniel Lewis read the next paper. It was justifiable to inquire what cases were curable, and to draw a line between them and cases which were incurable. It might be assumed that in all cases there was a time when cure could be effected by operative measures. But this stage was usually passed when patients applied for treatment at surgical clinics, a fact which hospital records demonstrated.

In the management of incurable cases, the most successful general tonic was indicated. On account of its depressing mental and physical effect, he had not for many years told a patient that she had cancer. Any other designation was preferable, as neoplasm, rodent ulcer, sarcoma. The friends, however, could be informed of the true nature of the disease. Occasionally surgical interference was indicated and different kinds of dressings called for. In cancer of the female breast, before ulceration the growth of the tumor had been decidedly retarded by hypodermic injection of ten minims of a twenty per cent. solution of chloride of aniline in alcohol. Almost without exception the patient had thus been relieved of pain. The agent was without color, thus being free from an objection to pyoktanin.

When ulceration of the surface occurred he applied an antiseptic dressing of antipyrine, drying the surface carefully, dusting the powder over it, covering with a thick layer of absorbent cotton, putting on a bandage to support the breast. In rare cases it was justifiable to operate in order to relieve the patient of the weight of the growth and disagreeable odor and discharge. Aristol had superseded iodoform. Opiates should be deferred as long as possible. Clay's Cheyenne turpentine, which had been used, abandoned, and again taken up at the London Cancer Hospital, had proven of benefit in cancer of the breast. An excellent dressing where it could be easily applied was a soft tampon saturated in ten per cent. solution of aristol and benzol.

Regarding palliative operations in cancer, nothing would relieve the patient so much, where the tongue was affected, as removal of the diseased mass, although cure was not expected. The same was sometimes true of cancer of the orbit. Moreover, recurrent cancer was usually less painful than the primary disease.

Cancer of the Female Genital Tract.—Dr. H. J. Boldt read a paper on this subject, leaving out the question of treatment. Primary cancer of the vulva was a great rarity. The majority of cases were complicated by disease of the vagina or uterus. The most common form was dermoid. It occurred most frequently between the fortieth and sixtieth years. Nothing definite was known of the etiology. A small, hard, rounded, irregular, slightly elevated mass was felt, covered by thick layers of scaly epithelium. The growth was slow, the symptoms slight at first; then the nodules became large, superficially denuded; pain then became a prominent symptom, purulent secretion of disagreeable odor, slight hemorrhage. It was unusual for the disease to pass to the other labium, but spreading took place toward the perineum, thigh, vagina, rectum. Death from septic infection perhaps in two to five years. Syphilis and lupus might, but should not, be mistaken for it. It was even more rare to find primary cancer of the vagina than of the vulva. It might occur during any period of life, but usually between the twentieth and fortieth years. Epithelioma might be large enough to obstruct the vagina. In other cases there were several smaller nodules. The course was rapid, and being usually recognized late, the prognosis was unfavorable, for the symptoms seldom attracted much attention on the part of the patient early in the disease. The first symptom noticed usually was hemorrhage after coitus. Examination would show a

hard induration surrounding an ulcer with indurated base, bleeding easily.

Cancer of the uterus was most frequent between forty-five and fifty. The cervix was oftenest affected, although cancer of the body was not rare. In all varieties the advanced stage led to induration of the broad ligaments and lymphatics, the exudative material going on to produce pressure upon the nerves, vessels, ureter. The bladder was frequently involved by extension, the rectum seldom. Hydronephrosis sometimes occurred from obstruction of the ureters. The division of cancer of the cervix according to location was of little practical importance to the practitioner. The forms were dermoid, scirrhous, adenoid, medullary. The adenoid form was most common, and it soon became transformed into the medullary form. Every adenoma of the cervix was likely to change into cancer. The etiology, as far as known, was catarrh with erosions, ulcerations, and lacerations. Regarding the symptoms, it was unfortunate that at the beginning stage they were so slight as to be overlooked. Frequently the patient was first impressed by hemorrhage at coitus, although leucorrhœa and perhaps some hemorrhage had existed before. Later the discharge often took on the appearance of meat-juice, and when exudative material became sufficient it caused pressure upon the nerves and pain in their area of distribution, sometimes œdema of the extremity. Nutrition began to suffer, the skin presented a pale yellowish hue. There might be uræmia from obstruction of the ureters. The principal cause of death was exhaustion; next, peritonitis; sometimes thrombosis of the iliac veins. When conception took place abortion was apt to occur about the third month, as stated by Hanks. The diagnosis of cancer of the cervix could not at the beginning be made without microscopic examination of some of the cervical tissue. Polypi hanging from the central canal could usually be distinguished from cancer of the cervix by careful examination showing a line between the tumor and cervix.

Primary cancer of the Fallopian tubes was rare, its existence being denied by some. Cancer of the ovary was not so rare.

Pain of Cancer Allayed by Electricity.—Dr. A. D. Rockwell thought the treatment of incurable cancer must be very incomplete without electricity. Some would remember a brief paper which he had recently read before the Society, describing a case in which strong currents through large electrodes alone had controlled the pain of cancer of the kidney. In this case it required more than 100 milliamperes, running up even to 175, to relieve the pain. Large clay electrodes were used. He thought the relief was chemical and mechanical, that the vaso-motor nerves were influenced, hastening circulation and thereby relief of pressure upon nerves of sensation.

Dr. A. F. Currier thought that if we compared the result of treatment fifteen years ago with that of to-day, it would be seen that advance had been made. The treatment was removal as early as possible. He did not think paste and powders were of much value in giving permanent results. In addition to the knife and scissors he recommended the cautery, which went more deeply into the tissues than could be done with the knife alone. Employ the most powerful tonics which would place the patient's general health on the highest plane possible.

Keep Down the Odor.—Dr. A. H. Smith recommended the preparation composed of sweet-almond oil charged with ozone for overcoming the fetor of cancer. He recommended cannabis indica for the relief of pain, which was free from most of the objections pertaining to opium.

Dr. Collyer recommended total removal of the disease if possible, and use of the knife for control of hemorrhage in uterine cancer under certain conditions. Cheyenne turpentine was apt to be impure. The actual cautery would check hemorrhage and prolong life. Codeia was less likely to lead to a habit than morphia.

After some further discussion, the Society adjourned to partake of the collation.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MENSTRUATION IN HEART DISEASE—ABDOMINAL SECTION FOR PERFORATION DUE TO GASTRIC ULCER—RESECTION AND SUTURE OF INTESTINE—MICROSCOPICAL AND BACTERIOLOGICAL DEMONSTRATIONS—DIPHTHERIA CULTURES—INFLUENZA BACILLI—MALARIA ORGANISMS—PULMONARY DISTOMIASIS—TROPICAL DISEASES—LAW CASES—LUNACY PROSECUTION—CHARGE OF NEGLIGENCE IN DIAGNOSIS—CONVICTION OF A QUACK—OPHTHALMOLOGICAL CONGRESS—DEATHS OF PROFESSOR HENRY SMITH AND DR. D. DAVIES.

London, March 31, 1894.

The relation of heart disease to menstruation was not very long ago discussed at the Royal Medical and Chirurgical Society, and it has lately been brought before the Obstetrical Society. The text-books speak of menorrhagia as a result of cardiac disease, and they go on copying each other, although long ago Dr. Mathews Duncan entered a caveat. The experience cited at the Society shows that on this point, instead of being a common accompaniment of heart disease, menorrhagia is rare; in fact, amenorrhœa is much more frequent. No doubt, on considering the tendency of valvular imperfections to produce congestions of viscera, some one put down as a guess that heart disease gave rise to menorrhagia, and the assumption once started has been promulgated as fact. Auscultation of applicants in the out-patient obstetrical departments of hospitals cannot elucidate such a point, for most of the women apply on account of some menstrual derangement. There seems a great tendency nowadays to dwell on the association of one disease with another, and the occurrence of some malady, during the progress of another, is chronicled as a discovery, while broader clinical features are sometimes neglected. Menorrhagia, often merely a temporary symptom, is therefore put down as connected with valvular imperfection of many years' standing, which is producing, perhaps, no other symptom.

Mr. Hutchinson was invested with the insignia of the Presidency of the Royal Medical and Chirurgical Society on the 13th, and the papers of the evening were appropriately surgical. One was by Mr. Morse, of Norwich, relating a successful case of abdominal section and suture for perforation of the stomach in a case of gastric ulcer. The diagnosis was made and operation resorted to within five hours. The contents of the stomach were found in the peritoneal cavity, which was washed out. The perforation was found and closed. The patient was well in three weeks. Some interesting remarks were made by several surgeons, and Mr. Morse was congratulated by the President on his success.

Mr. Lockwood then related a case of resection and immediate suture of an intestine which had been strangulated eighty-one hours. This was the first case he had been able to treat thus since he proposed the plan at this Society in 1891. Mr. Lockwood considered as factors in his success, the care taken to avoid death from shock by the cessation of the anæsthetic, the application of warmth and stimulants, speed in operating, disinfection of sac and protection of the peritoneum from infection, and absence of intestinal paralysis at the time of operating. We have lately had some interesting microscopical bacteriological papers. Thus at the Medical Society on the 17th, Dr. Wethered related his further investigations on diphtheria cultures. These give considerable aid in diagnosis, but can only be carried out in hospitals or laboratories properly furnished for the purpose. It is not always easy to distinguish diphtheria from follicular tonsillitis by the naked eye, but Dr. Wethered thinks there is no danger of mistaking the organisms of each under the microscope, and in case of doubt cultures should be made. At another society Dr. Kanthack demonstrated pure

cultures of influenza bacilli on both gelatine and agar-agar. This bacillus he found always present in the bronchial secretion in influenza, and, as it is not found in any other disease, is probably the cause. It is not commonly found in the blood, but Dr. Klein, when ill, found it in his blood as well as in his sputum. Dr. Kanthack also showed specimens of the streptococcus of pneumonia, and pointed out the distinction between that and the bacillus of influenza.

The organisms of malaria were exhibited at a third society (Hunterian) by Dr. Manson. They are delicate, and it is difficult to transport them. Those shown were crescentic bodies, stained with methyl-blue, and in the centre were dark pigmented spots. Other forms were described by Dr. Manson, the relations of which to each other have not been determined. Two forms now well known were, he said, 1, the intra-corpuscular with pale black pigment in the centre, and showing amœboid movement at the edge, and, 2, the central spherical mass of pigment to which flagellæ are attached, while a third form consists of oval, egg shaped, red bodies. Dr. Manson also showed microscopic specimens of sputum containing ova from a case of pulmonary distomiasis, a common disease in China and Japan. The parasite lives in burrows in the bronchi and in the lung substance, where the ova are deposited and then coughed up in myriads. The cough is spasmodic and the sputum sanguineous, thus suggesting aneurism, which is so common in the East that when these symptoms occur with a history of acute hemorrhage the first diagnosis is, said Dr. Manson, always aneurism, but the sputum should he examined to eliminate distomiasis. He spoke of aneurism as being as common in the East as phthisis in London. He also said this distomiasis may affect the brain, giving rise to typical Jacksonian epilepsy, and suggested that such cases might be treated surgically. A week or more previously Dr. Manson read a paper at the North London Society, on "Tropical Diseases," which he illustrated by microscopic preparations and lantern slides. In that paper he treated both of malaria organisms and the filariæ. It will be seen, therefore, that he is doing much to disseminate the results of his great experience in the East, for which his stay-at-home brethren are naturally thankful.

We have lately had some important proceedings in the law courts. A doctor at Eastbourne was prosecuted by the Lunacy Commissioners for having more than one patient of unsound mind in his house at the same time. He was acquitted, and the judge spoke highly of his conduct in relation to his patients. At the same time the Commissioners were said to have only fulfilled their duty in prosecuting. This shows the necessity of care in receiving doubtful cases, and the danger to which a doctor who takes such patients is exposed. Should every patient who is at times certifiable be certified? If not, those who receive them should be in some way protected from such prosecutions. Perhaps it could be done by means of consultations. The patient's private attendant and a specialist in lunacy might consult and reduce to writing their opinion that the case was not one for an asylum but would benefit by medical supervision. Armed with such a certificate, which could be renewed from time to time, the medical man who took charge of such a patient would be better able to defend himself if prosecuted.

A lady brought an action against her attendant for negligence in not diagnosing small-pox when first called to see her servant. There was some contradictory evidence and the jury pronounced in favor of the doctor, but he will be a loser no doubt in pocket, and his mental anxiety must have been great. Here is another illustration of the dangers to be encountered in practice and the necessity of being awake to the possibility of the invasion of an infectious disease when there is no reason to suspect exposure.

Another trial is more satisfactory. An advertising quack has been convicted of having obtained sums of money by fraudulent pretences. It was a very bad case, and the judge regretted he could not give more than five years' penal servitude. That term, however, may be enough for the convict to reflect on the folly of his course. He is an old offender, and the police had no little difficulty in securing evidence. He had been a bill-poster, but set up as a curer of diseases, and obtained patients by placarding public conveniences and advertising. In the case on which the prosecution was entered he had squeezed the last penny from a poor Irishman, who went to Liverpool to see him.

The Eighth International Ophthalmological Congress promises to be a success. Already more than two hundred ophthalmologists have intimated their intention of going to Edinburgh for the occasion, so that August will be lively in the northern capital.

Yesterday the remains of Mr. Henry Smith, F.R.C.S., were committed to the grave. He died on Sunday, aged seventy. His name will be familiar to you as the author of the "Surgery of the Rectum," and as Surgeon to King's College Hospital (lately Consulting Surgeon and Emeritus Professor). He was for a long time closely associated with the late Sir William Ferguson, whose assistant he was at King's.

Another death is that of Dr. David Davies, aged seventy-six, who did good service to Bristol as its medical officer of health for twenty-one years. On his retirement his son was appointed to the office.

THE USE OF PURGATIVES IN THE TREATMENT OF TYPHOID FEVER.[1]

To the Editor of the Medical Record.

Sir: In regard to the use of purgatives in typhoid fever, I would refer to some facts which are a matter of history.

This means of treatment was in use long before Delarroque published his experience with it.

Indeed, he recognizes himself that he took his idea from writers of a previous period, and principally from Stoll. But as Valleix[2] says, "If we can draw from these writings like inspiration, we cannot feel authorized, from statements they make or which are there indicated, to judge of the efficacy of remedies." The reason of this is evidently based on the fact that the diagnosis of typhoid fever was not at that time clearly determined. It was Beau who first published the results obtained by Delarroque with the use of purgatives, at the Necker Hospital in Paris, where the mortality was ten per cent. Later Delarroque published the same facts,[3] and in 1847 his work on typhoid fever appeared, which was evidently destined to show that the fever is due to alteration of the bile, and that the method by free evacuation of the bowels has a manifest superiority over every other form of treatment. Andral, also, made free use of purgatives in the treatment of typhoid fever, and had a somewhat larger mortality than Delarroque.

The observations of Louis and Barth go to show that the action of purgatives is not injurious in typhoid fever, and that very probably they have a beneficial effect upon the issue of the disease, although the malady did not appear to be shortened by their use. The purgatives employed by the authors cited, were seidlitz-water, castor-oil, and calomel. "One of these purgatives must be given every day; and if they are alternated, it is done merely so as not to fatigue the patients, for the essential matter is to purge." It has been said that the use of purgatives in typhoid fever occasioned intestinal hemorrhage. It is probable when hemorrhage took place, it was a mere coincidence. In the large number of typhoid patients formerly treated with purgatives, intestinal hemorrhage rarely occurred. Not only is this true, but it is also occasionally true that intestinal hemorrhage seems to be really brought on by the constipation from which

[1] This communication is prompted by an article in your issue of March 10, 1894, entitled "Eliminative and Antiseptic Treatment of Typhoid Fever," and by a letter from Dr. Osler in Medical Record of March 31, 1894.

[2] Guide du Médecin Praticien, vol. i., p. 44.

[3] Bull. de l'Acad. de Méd., Paris, 1837, t. i., p. 482.

the patient suffers. As an instance of this, I would offer the following case:

S. M——, twenty eight years of age, married, English, housewife, entered my service at St. Luke's Hospital on December 30, 1893. At that time she had all the usual symptoms of typhoid fever at the eighth day of the disease. Tub-bath treatment was immediately begun. Patient progressed favorably until the seventeenth day of the disease. On that day patient was comfortable. In the afternoon she had a large, light-colored, constipated stool, which was accompanied with the loss of two ounces of fluid red blood. Five minims of Magendie's solution were administered hypodermically, the ice-coil applied over the abdomen, and the tub-baths discontinued. The hemorrhage did not recur, and there were no subjective symptoms from the one referred to. The following day I ordered the following laxative: Mass. hydrarg., gr. j.; syrupi rhei aromat., and olei ricini, āā ʒ j. This dose was followed by four large, formed stools, without any hemorrhage. Patient was feeling very comfortable. Four days later another laxative dose was given with good results, and in view of a tendency to constipation; subsequently, patient progressed toward recovery and is now convalescent.

I am confident, in this case, that the constipated condition of the bowels was the immediate cause of the slight intestinal hemorrhage. Not to have administered a laxative would have been bad practice, and would probably have led to recurrence of more abundant hemorrhage. I may add that I have frequently known fever to continue in typhoid fever, especially toward its terminal period, and not to disappear, despite other treatment, until laxatives had been repeatedly taken.

The most important indication, in case of intestinal hemorrhage, writes Liebermeister,[1] "is to limit the movement of the bowels, as far as possible, and therefore the main remedy employed is opium in small doses." In instances similar to the one of which I have just given a short abstract, treatment with opium would have increased the difficulty, and thus no doubt brought on another and more severe loss of blood from the bowel. Of course, one should always bear in mind in such cases, "that the quantity of blood which appears in the stools is by no means a reliable measure of that actually lost, as more blood frequently remains in the intestines than appears externally."[2]

Still, the rapid fall of temperature, feebleness of pulse, extreme prostration, and sudden pallor will usually indicate its severity, and may be regarded as a guide to the danger of giving laxatives.

Baglini's advice, now two centuries old, of avoiding the use of active cathartics in the treatment of typhoid fever, should not be invariably followed, not even when there is slight or moderate intestinal hemorrhage. It is for the physician to weigh carefully the accompanying conditions, and to act in accord with sound judgment when it is question of active interference. The treatment by an occasional purgative, by intestinal antisepsis, and by the free use of water by the mouth, has been considered eminently rational by the writer in many cases of typhoid fever. The attention of my house staff at St. Luke's Hospital has been directed to it on several occasions during the past and former winters. Although this statement is made, I am willing to add that I now advocate, as a wise supplementary method in many instances, the treatment with cold baths. It is just and broad-minded, however, not to ignore the experience of the past, and to give due credit to those who have preceded us in our work.

BEVERLEY ROBINSON, M.D.

Carbolic Acid in Tetanus.—Carbolic acid, in doses of one-half centigramme, repeated every one or two hours, is said by Bacelli to cure tetanus.

PURGATIVE TREATMENT OF TYPHOID.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In a recent issue Dr. Osler reminds me that I must not claim to be the introducer of purgation as a method of treatment in typhoid fever, and points out that M. Larroque, of Paris, advocated purgation so far back as 1841. I can assure Dr. Osler that I should be the last in the world to claim credit for what did not properly belong to me. However, if Dr. Osler had honored my paper with more than a cursory glance he would have seen that I made no such claim. I am not novice enough to be unaware that so primitive and general a therapeutic procedure as purgation had in all probability been applied in this disease. Even had I never heard of the old humoral pathology or of the attempts to deliver the body of its harmful occupant by bleeding, purging, sweating, etc., yet the reiteration of warning against purgation in all the text-books I had ever seen and in all the lectures I had ever heard must have told me that I could not have been the first to advocate this practice. What I did claim to have introduced was a plan of treatment very much at variance with the present teaching, and having as its objective point removal and destruction of the bacillus and its toxic product. The several features of this plan, together with the views regarding their interdependence and the necessity for their association, are, I think, clearly set forth in the published paper, MEDICAL RECORD, March 10th.

Yours, etc.,

W. B. THISTLE.

TORONTO, April 15, 1894.

Therapeutic Hints.

Multiple Warts of the Face.—

Flowers of sulphur	grammes	20
Glycerine	"	50
Pure concent. acetic acid	"	10

Encephalitis following Contusion.—We should treat such an inflammation precisely as we would treat it in other regions of the body, always remembering that in the brain, by reason of the bony case in which it is retained, it is impossible for an exudation or hemorrhage to find its way to the surface without surgical assistance. —KEEN.

Psoriasis.—

Ichthyol,
Salicylic acid,
Pyrogallic acid,
Aristol.....āā grammes 2½.
Vaseline,
Lard,
Lanoline.....āā grammes 30.

This salve is very active, and should only be used in very small quantities.

—BESNIER.

Pain after vaginal douche may be due to water entering the uterus. Laudanum enemata are advised. Order douche only lying on back and with a not too strong jet. —ROULIN.

Epilepsy.—

Bromide of potassium	100	parts.
Tincture of calabar bean	35	"
Water	470	"

Give ʒ iv. increased to ʒ vj. and finally to ʒ j. daily.

—POULET.

Bilious Remittent Malarial Infection.—Rectal injections of carbolic acid. Hypodermics of quinine. For the profound nervous depression:

℞. Sodium arsenate..... gr. iij.
Strychnia sulphate..... gr. jss.
Distilled boiled water..... ℥ xss.
S. Teaspoonful.

—PEPPER.

Medical Items.

Contageous Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 21, 1894.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	10	7
Scarlet fever	123	19
Cerebro-spinal meningitis	2	4
Measles	286	28
Diphtheria	181	62
Small-pox	19	3
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

Children's Diseases in Constantinople.—In the Pediatric Section of the recent Congress, Dr. Violi read a paper on the diseases of children most commonly occurring in Constantinople. Typhoid fever was very common prior to the seventh year, assuming sometimes a severe and sometimes a mild form. The best treatment consisted in free ventilation of the sick-room, cold sponging, and small doses of phenacetine. He had abandoned the use of quinine, which was difficult of administration to children and was moreover of little use. Dengue and influenza had, he said, many points of resemblance, yet it was not difficult to differentiate the two affections at a time when both were epidemic in his city. The most common diseases among children in Constantinople are those of the respiratory organs. Rachitis is also very frequent by reason of the defective alimentation of infants among the poorer classes.

The Next International Congress of Gynecology will be held in Geneva, Switzerland, in September, 1896.

Death from Gluttony.—A boy, fifteen years of age, living in London, spent his Easter holiday in Blackheath, where he ate thirty oranges, a whole cocoanut, and a mince pie, quenching his thirst with cider and various effervescent drinks. In the evening he had several cups of tea, and later some cake and lemonade. Before the dawn of the following day he was dead, and the coroner's jury brought in a verdict of "death from natural causes."

The Cholera in Constantinople is on the increase. The director-general of the tobacco monopoly in Turkey died of the disease recently, and as he had previously eaten of oysters, the government came to the conclusion that that was the cause of the growing epidemic, and has consequently issued an edict prohibiting the sale of shellfish of any kind.

The Roman Press on the Congress.—The daily papers of Rome were unsparing in their denunciation of the management of the Congress, the organization of which they described as "iniquitous," a disgrace to Italy and to Rome, and an insult to the medical profession of the world. It really was not quite as bad as that, though far from perfect.

Troglodytism and Alcoholism as Etiological Factors in Tuberculosis.—Dr. Tison, of Paris, read a paper with this title in the Section on Hygiene at the Rome Congress, in which he compared modern habitations to the holes of the troglodytes. In many warehouses, offices, and banks in the larger cities artificial lights must be kept burning all day, and even in many sleeping-rooms the rays of the sun never penetrate. This mode of living is a fruitful predisposing cause of tubercular disease. The speaker held that all buildings in cities should be constructed with a large open court, not a mere well, where the sunlight could enter freely, so that the inside rooms could receive as much light and air as those facing the street. Referring then to the abuse of alcoholic beverages, the speaker said that their habitual consumption in large quantities, even short of drunkenness or inebriety, predisposed the organism to attacks by the tubercle bacilli. When these two factors act in concert tuberculosis is almost sure to result. Alcohol is a stupefying poison, and should be given only in medicinal doses, just as digitalin, strychnine, and other drugs of the class.

The Physical Diagnosis of Gall Stones.—Gerhardt observes that the attack usually begins four to five hours after the chief meal, that is, shortly after the entrance of the stomach contents into the duodenum. According to the size and position of the stone after it has passed into the common bile duct, distention of the gall-bladder may be recognized at once, or later (when the gall-bladder has been copiously filled), or not at all. The swelling lies between the right parasternal line and the anterior axillary line, mostly a little to one side of the right rectus muscle. If the gall-bladder is much distended it may give rise to errors in diagnosis. This distention only takes place in a minority of the cases. It may be absent owing to the smallness of the gall-bladder, or to the obstruction being incomplete, or lasting too short a time. It occurs in severe attacks, or in those who have had repeated attacks. The commencement of the attack may last a couple of hours without pain, during which time the gall-bladder may be palpable. The shrinking of the swelling shows the end of the attack. After a severe attack a friction sound, synchronous with inspiration and expiration, and sometimes of diagnostic value, may be heard over the gall-bladder. This is due to local peritonitis, and it explains the continuance of the pain. An ice-bag is more useful here than warm applications. The liver may swell after severe attacks and fever be present. Attacks may occur with pain and fever, but there is neither swelling of the gall-bladder nor of the liver, and no stone is found in the stools. It is thought that the stone slips back into the gall-bladder, but other possibilities exist The swelling of the gall-bladder may be due to obstruction having other causes, but it does not occur in cardialgia, nor in hepatic colic of purely nervous origin. This latter is observed in tabes, hysteria, multiple sclerosis, and may even be accompanied by jaundice. When, after several attacks no stone is found, no friction sound heard, and no swelling of the gall-bladder felt, cholelithiasis may, with tolerable certainty, be excluded, and neurotic hepatic colic may be assumed with great probability.—*The British Medical Journal.*

The Cataracts of Mr. Gladstone.—The truth respecting Mr. Gladstone's eyesight has at last been made public, and the ophthalmic surgeon under whose care the ex-Premier has placed himself is Mr. Nettleship. We understand, says *The Medical Press*, that Mr. Nettleship was recommended to the aged statesman by Sir James Paget, who is a personal friend of Mr. Gladstone's. The rumor that cataract was present in each of Mr. Gladstone's eyes is confirmed, and there consequently remains nothing more to be done than extraction of the lens from one or both eyes, in order to restore vision. Report states, however, that no operative interference will be undertaken until the lapse of six months. Probably this course has been decided on with the view of allowing the good effects of rest from the anxious cares of the leadership of his party to become more manifest in Mr. Gladstone's health.

Charcot's Successor.—Dr. F. Raymond has been recommended by the Paris Faculty of Medicine for appointment to the Chair of Clinical Neurology, vacant by the death of Professor Charcot.

Sir Henry Thompson likes telescopes as well as endoscopes and has recently offered to give $25,000 for the purchase of a new instrument for the Greenwich Observatory.

DIGESTIVE PROTEOLYSIS.

THE CARTWRIGHT LECTURES FOR 1894.

BY R. H. CHITTENDEN, PH.D.,

PROFESSOR OF PHYSIOLOGICAL CHEMISTRY IN YALE UNIVERSITY.

(Continued from page 517.)

LECTURE III.

PART I.—PROTEOLYSIS BY TRYPSIN.

IN pancreatic digestion proteids are exposed to the action of an enzyme of much greater power than pepsin, one endowed with a far greater range of activity, and consequently proteolysis, as it occurs in the small intestine, becomes a broader and more complicated process. As you well know, the ferment trypsin manifests its power not only in a more rapid transformation of insoluble proteids into soluble and diffusible products, but there is a diversity in the character of the many products formed which testifies to the profound alterations this ferment is capable of producing. The primary and secondary products of pepsin-proteolysis, as well as unaltered proteids, are alike subject to these changes, and bodies of the simplest constitution may result in both cases from the series of hydrolytic changes set in motion by this proteolytic enzyme. The power of the ferment as a contact agent is astonishing, for in the case of trypsin no accessory body is necessary to bring out its latent power. Water, proteid, and the enzyme at the body temperature are all that is necessary to call forth prompt and energetic hydrolytic action.

Moreover, hydrolysis does not stop with the mere production of soluble proteoses and peptones, but the hemiportion of the latter is quickly broken down into crystalline bodies, such as leucin, tyrosin, lysin, lysatin, etc. This special characteristic of the ferment testifies in no uncertain manner to the existence of inherent qualities in the inner structure of the enzyme peculiar to the body itself. In general properties and reactions, pepsin and trypsin may be closely related; both are products of the katabolic action of specific protoplasmic cells, but the inner nature or structure of the two must be quite different. Pepsin, as we have seen, is powerless to produce any change in proteid bodies unless acids are present to lend their aid. Furthermore, pepsin is limited in its action to the production of proteoses and peptones, while trypsin gives rise to a series of hydrolytic cleavages which result in the ultimate formation of comparatively simple bodies.

Trypsin, however, in its natural environment is dissolved in an alkaline medium. Its proteolytic action is therefore carried on, under normal circumstances, in an alkaline reacting fluid containing 0.5 to 1 per cent. sodium carbonate, and the proteolytic power of the ferment is unquestionably manifested to the best advantage in such a medium. At the same time it will act, and act vigorously, in a neutral fluid, and likewise in a fluid having a weak acid reaction, provided there is little or no free acid present. Thus, in experiments[1] on blood fibrin it was found that, while a solution of trypsin containing 0.5 per cent. sodium carbonate, digested or dissolved 89 per cent. of the proteid in three to four hours at, 40° C., a perfectly neutral solution of the ferment, otherwise under exactly the same conditions, digested 76 per cent, and a 0.1 per cent. salicylic acid solution of the enzyme converted 43 per cent. of the proteid into soluble products.

With hydrochloric acid, trypsin is quickly destroyed, unless there is a large excess of proteid matter present,[1] which obviously means that the acid in such case exists wholly as combined acid. Indeed, experiments made in my laboratory have shown that as soon as free acid, especially hydrochloric, is present in a solution containing trypsin, then proteolytic action is at once stopped. When, however, acids, especially organic acids, are present in a digestive mixture containing an excess of proteid matter, so that the solution contains no free acid; or better, with the proteid matter only partially saturated with acid; then trypsin will continue to manifest its peculiar proteolytic power, although to a considerably lessened extent. Hence, it is evident that the ferment may exert its digestive power under the three possible sets of conditions which, under varying circumstances, frequently prevail in the small intestine.

In considering the general phenomena of proteolysis by trypsin, one is especially impressed by the large and rapid formation of peptone which almost invariably results, from the action of a moderately strong solution of the ferment, on nearly every form of proteid matter. To be sure, primary products are first formed, but these are quickly converted into peptone, and a little experience in studying the action of pepsin and trypsin soon reveals the fact that the latter is especially a peptone forming ferment. In other words, it is peculiarly adapted to take up the work where it has been left by pepsin, and if necessary, carry forward the hydrolytic change even to the extent of a conversion of the entire hemi-moiety into crystalline products.

The primary products of trypsin-proteolysis, however, are not exactly identical with those formed by pepsin. Thus, protoproteoses and heteroproteoses seldom appear in an alkaline trypsin digestion; the proteid matter being in most cases, at least, directly converted into soluble deuteroproteoses,[2] which are then transformed by the further action of the ferment into peptones and other products. Hence, we may express the order of events in the trypsin digestion of a native proteid as follows:

Native proteid.

Amphodeuteroproteoses.

Amphopeptones.

Antipeptone. Hemipeptone.

Leucin. Tyrosin. Aspartic acid, etc.

In the digestion of fresh blood-fibrin with trypsin, there is plainly a preliminary solution of the proteid without

any marked transformation or cleavage occurring, the soluble product being apparently a globulin, coagulating at about 75° C.,[1] viz., at approximately the same temperature as serum-globulin. This body, however, quickly disappears, giving place to true deuteroproteoses as the ferment action commences; for it is not probable that this globulin is a product of enzyme action, but rather represents a simple solution of the fibrin by the alkaline fluid and salts. In any event, this globulin-like substance is not formed in the pancreatic digestion of coagulated-albumin, serum-albumin, or vitellin, and hence cannot be considered as a true product of trypsin-proteolysis.

The fact that deuteroproteoses are the primary product of trypsin digestion again emphasizes the natural adaptability of this ferment to the part it has to play in the digestive process. Its natural function is to take up the work where left by pepsin, and carry it forward to the necessary point; and hence, when acting upon a native proteid the primary products of its action correspond to the secondary products of pepsin-proteolysis. Trypsin is thus equally efficient in the digestion of all native proteids, but the products of such action are always deuteroproteoses, peptones, and crystalline amido-acids. It is to be remembered, however, that in trypsin-proteolysis the deuteroproteoses and the amphopeptones must necessarily be represented by bodies in which there is a preponderance of anti groups. In pepsin-proteolysis, as we have seen, the hemi and anti groups of the proteid molecule remain more or less united, but in pancreatic digestion, the formation of amphopeptone is quickly followed by the breaking down of a portion of the hemipeptone into leucin, tyrosin, etc. thus leaving a larger proportion of the anti moiety in the remaining amphopeptone.

Theoretically, at least, in the case of a vigorous and long-continued pancreatic digestion, all of the hemipeptone formed from any native proteid can be converted into crystalline and other products, thus leaving a true antipeptone resistant to the further action of trypsin. Hence, we are prone to speak of the peptone of pancreatic digestion as antipeptone, although, as can be readily seen, the exact nature of the peptone, *i.e.*, the relative proportion of hemi and anti groups it contains, will obviously depend upon the length of the digestion and the strength of the ferment. Again, it is possible, as certain facts seem to suggest, that the amido-acids which are so readily formed from hemipeptone may come in part directly from the hydration of a portion of the hemideuteroproteose, without passing through the preliminary stage of hemipeptone. If so, we have another source of variation in the relative proportion of hemi and anti moieties in the deuteroproteoses and peptones of pancreatic digestion. Still again, it is to be remembered that in normal digestive proteolysis, as it occurs in the living intestinal tract, the proteid matter to be acted upon has already passed through certain preliminary stages in its transit through the stomach, as a result of which still further variations in the proportion of hemi and anti groups may be possible.

It is thus plainly evident, in view of the ready cleavage of the hemi-group into amido-acids, that the primary products of trypsin proteolysis, the proteoses and peptones must necessarily be composed in great part of those complex and semi resistant atoms which we include under the head of the anti group. However much one may be sceptical about the real existence of so-called hemi and anti groups, there is no gainsaying the fact that a given weight of native proteid, like egg albumin or blood-fibrin, cannot be converted wholly into crystalline or other simple products by trypsin; indeed, it is quite significant that, at the end of a long-continued treatment with an alkaline solution of the pancreatic ferment, there is usually found about fifty per cent. of peptone, while the other fifty per cent. of the proteid is represented mainly by more soluble products, such as the amido-acids. It is also significant that the peptone obtained from an artificial pancreatic digestion, where the proteolytic action has been long-continued and vigorous, resists the further action of the ferment. In other words, it is the so-called antipeptone. In line with this result is the fact that the peptones formed in pepsin-proteolysis, when treated with an alkaline solution of trypsin, are converted into amido-acids and other bodies of simple constitution to the extent of about fifty per cent. This is easily explainable on the ground that the hemi portions of the above peptones are broken down into simple products, while the anti portions remain unchanged, being resistant to the ferment and thus leading to a separation of the two groups, or at least to the isolation of the anti molecules.

There is much that might be cited in further support of these views, but doubtless I have said enough to make it plainly evident that in the pancreatic digestion of any native proteid, not more than one-half can at the most be transformed into crystalline products, while the other half will be represented mainly by a peptone incapable of further change by trypsin. Similarly, the products of pepsin-proteolysis exposed to the action of trypsin may undergo a like separation, the hemi groups only breaking down into simple products. Hence, the whole theory of the hemi and anti moieties of the proteid molecule means simply that, of the many complex atoms composing the molecule, one-half are easily decomposable by the pancreatic ferment, while the other half are more resistant and make up the so-called anti group.

In any active pancreatic digestion of either a native proteid, or of the products of pepsin-proteolysis, the anti group is represented mainly by antipeptone, although there is often found a small amount of a peculiar antialbumid-like body, insoluble in the weak alkaline fluid. Antipeptones, thus far studied, when entirely free from proteoses, are characterized by a low content of carbon, like the amphopeptones from pepsin-proteolysis. The following table shows the composition of a few typical examples:

Composition of Antipeptones.

	From blood-fibrin.[1]	From blood-fibrin.[2]	From antialbumose.[3]	From casein.[4]	From myosin.[5]
C	47.30	49.59	48.94	49.94	49.26
H	6.73	6.92	6.65	6.51	6.87
N	16.83	15.79	15.89	16.30	16.62
S	0.73	—	—	0.68	1.16
O	28.41	—	—	26.57	26.09

From these data it is evident that, while each individual peptone may have a composition peculiar to itself, they are all alike in possessing a relatively low content of carbon. The antialbumid, however, split off in these hydrolytic changes, like the antialbumid formed by the action of dilute acids at 100° C., is characterized by a correspondingly high content of carbon and a low content of nitrogen. As an illustration may be mentioned the myosin antialbumid formed in the digestion of myosin from muscle tissue by an alkaline trypsin solution. This body contains 57.48 per cent. of carbon, 7.67 per cent. of hydrogen, 13.94 per cent. of nitrogen, 1.32 per cent. of sulphur, and 19.59 per cent. of oxygen.[6] It is only necessary to compare these figures with those expressive of the composition of myosin antipeptone, to appreciate how wide a gap there is between these two products of trypsin-proteolysis, and both members of the anti group. Antialbumid, however, is a peculiar product, one which is liable to crop out somewhat unexpectedly, and with varying shades of resistance toward the proteolytic ferments. As formed in pepsin-proteolysis, it is more or less readily soluble in sodium carbon-

ate, and in part readily convertible into antipeptone by trypsin. Still, the same substance, or at least a closely related body, makes its appearance in the form of an insoluble residue whenever a native proteid is digested by trypsin. At times, the amount of this insoluble product may be quite large, even reaching to one-fourth of the total proteid matter ;[1] but when so formed in the intestine it must entail a heavy loss of nutriment, for whenever the anti group is split off after this fashion it becomes very resistant to the further action of the ferment. Separating in this manner from an artificial digestive mixture, it may be dissolved in dilute caustic alkali, reprecipitated by neutralization, and then once again brought into solution with dilute sodium carbonate. In this form it will yield some antipeptone by the further action of trypsin, although even then a large amount of the antialbumid is prone to separate out as a gelatinous coagulum, resistant to the action of the ferment.

The peculiar action of trypsin, however, as a proteolytic enzyme is shown in the production of a row of crystalline nitrogenous bodies of simple constitution whenever the ferment is allowed to continue its action for any length of time, either on native proteids or on proteolytic products containing the hemi group. This, to be sure, is a fact long known, but it gains added significance as year by year new bodies are discovered as products of trypsin-proteolysis with various forms of proteid matter. The very character of the bodies originating in this manner gives evidence of the far-reaching decompositions involved ; decompositions which are perhaps attributable as much to the innate tendencies of the proteid material as to the specific action of the ferment. As representatives of this peculiar line of cleavage, we have first the well-known bodies, leucin and tyrosin ; leucin, a body belonging to the fatty acid series, known as amido caproic acid, $CH_3 (CH_2)_3 CH (NH_2) COOH$; and tyrosin, a body belonging to the aromatic group, having the formula $C_6H_4 <^{OH}_{CH_2} CH (NH_2) COOH$, and known as otyphenol-amido-propionic acid.

These two bodies are therefore representatives of two distinct groups or radicals present in the hemi portion of the proteid molecule ; the first belonging to the fatty acid series, the second to the aromatic group from which come such well-known bodies as indol, skatol, benzoic acid, and other substances prominent in proteid metabbolism. Moreover, these two hydrolytic products of trypsin-proteolysis are formed in considerable quantity, at least in an artificial digestion. Thus, Kühne has reported the finding of 9.1 per cent. of leucin and 3.8 per cent. of tyrosin as the result of a typical digestion, and I have tried many similar experiments with like results. Further, we know from observations made by different investigators that both leucin and tyrosin may be formed in considerable quantities in trypsin-proteolysis as it occurs in the living intestine. But to this point we shall return later on.

Besides leusin and tyrosin, aspartic acid and glutamic acid have long been known as decomposition products of the vegetable proteids. Thus, both acids were discovered by Ritthausen and Krensler[2] in the cleavage of such proteids by boiling dilute acid. Hlasiwetz and Habermann[3] likewise obtained aspartic acid in large quantity by the breaking down of animal proteids under the influence of bromine. Further, Siegfried[4] has recently obtained glutamic acid as a product of the decomposition of the phosphorus-containing proteid, reticulin, from adenoid tissue. As products of trypsin-proteolysis, Salkowski and Radziejewski[5] found aspartic acid in the digestion of blood-fibrin ; and v. Kineriem[1] likewise obtained it in the digestion of gluten from wheat. Both of these acids belong to the fatty acid series, the aspartic acid being a dibasic acid, $COOH.CH_2 CH (NH_2) COOH$, or amido-succinic acid, while glutamic acid, $COOH. C_3 H_5 (NH_2) COOH$, is likewise a dibasic acid, known as amido-pyrotartaric acid.

Of more interest, physiologically, are the recently discovered nitrogenous bases lysin and lysatinin, or lysatin. These two bodies were first identified by Drechsel[2] and his co-workers as products of the decomposition of various proteids, when the latter are boiled with hydrochloric acid and stannous chloride. They were first obtained by Drechsel as cleavage products of casein.[3] Later, Ernst Fischer,[4] working under Drechsel's direction, separated them as decomposition products of gelatin ; while Siegfried[6] obtained them as products of the cleavage of corn-glutin, glutenfibrin, hemiprotein, and egg-albumin, by boiling with hydrochloric acid and stannous chloride. In all of these cases it is obvious, from the method of treatment pursued, that the two bodies result from a simple hydrolytic cleavage of the proteid molecule. Hence, it might be assumed that these two bases would likewise be formed in trypsin-proteolysis. This assumption, Hedin,[6] working in Drechsel's laboratory, has proved to be correct, and furthermore he has shown that the amount of these bases formed in pancreatic digestion is not inconsiderable. Thus, as products of the digestion of three kilos. of moist blood fibrin with an alkaline solution of trypsin, 28 grammes of pure platino-chloride of lysin were obtained, and sufficient lysatinin to establish its identity.

Lysin has the composition of $C_6 H_{14} N_2 O_2$, being a diamido-caproic acid, a homologue of diamido-valerianic acid. Hence, this body, like leucin or amido-caproic acid, is a representative of the fatty acid group, the chemical relationship between the two bodies being plainly apparent from their constitution. The constitution of lysatinin is less definitely settled, but apparently it has the composition of a creatin, its formula being $C_6H_{13}N_3O_2$, in which case it might be more appropriately termed lysatin. The special point of interest, however, connected with this latter body as a product of trypsin-proteolysis is the fact that by simple hydrolytic decomposition, all chance of oxidation being excluded, it can break down into urea.[7] For years, chemists have been seeking to trace out the line of cleavage or decomposition by which urea results in proteid metabolism. In the nutritional changes of the body, nearly all the nitrogen of the ingested proteid food is excreted in the form of urea, but chemists working with dead food-albumin have been heretofore unable to break down proteid matter directly into urea. This, however, Drechsel has now succeeded in doing, and it is to be especially noted that the line of decomposition or cleavage is simply one of hydration, in which the proteid molecule, either through the action of boiling dilute acids, or through the more subtle influence of the hydrolytic enzyme, trypsin, is gradually broken down into cleavage products from one or more of which comes lysatin. The very resemblance of this body to creatin suggested that, since the latter breaks down into urea and sarcosin when boiled with baryta water, lysatin might possibly behave in a similar manner. This, as has been previously stated, was found to be the case, and Drechsel obtained from ten grammes of a double salt of lysatin and silver one gramme of urea nitrate, by simple boiling with baryta water.

It is thus evident that a certain amount of urea may come from the more or less direct hydrolysis of proteid matter in the intestinal canal, all but the last steps in the process being the result of the ordinary cleavage processes incidental to trypsin-proteolysis. This fact affords additional evidence of the profound changes set in motion by this proteolytic enzyme. It is not, of course, to be understood that all the urea formed in the body has its origin in this manner. Such a method of decomposition taking place in the intestinal tract would be exceedingly unphysiological and wasteful, but we can readily see how such a line of cleavage might result in inestimable gain to the economy in cases where excess of proteid food has been ingested. Under such circumstances, a portion of the surplus might be broken down directly in the intestine into this urea antecedent, and thus quickly removed from the system with a minimum amount of effort on the part of the economy. Drechsel estimates that about one-ninth of the urea daily excreted may come from the direct decomposition of lysatin, the latter obviously having its origin in trypsin-proteolysis.

Another product of trypsin-proteolysis which has long been recognized, although its real nature has not been known, is tryptophan or proteinochromogen. This body is not only a product of the pancreatic digestion of proteids, but it is also formed whenever native proteids are broken down through any influence whatever, the substance coming presumably from the hemi moiety of the molecule. It is especially characterized by the bright-colored compound it forms with either chlorine or bromine, so that for a long time it went by the mystical name of the "bromine body." When brought in contact with either of these agents, it immediately combines with them to form a new compound of an intense violet color, termed proteinochrome. This constitutes the usual test for its presence, a little bromine water, for example, quickly bringing out a violet color when added to a fluid containing the chromogen. The body is readily soluble in alcohol, and hence can be easily separated from the primary products of trypsin-proteolysis such as the proteoses and peptones. Krukenberg considered the substance not a true proteid, but rather a body belonging to the indigo group; but Stadelmann, who has given the matter a very thorough investigation, comes to the conclusion that it is truly a proteid body, in part closely related to peptone, although in many ways quite different. The following composition of bromine proteinochrome, as determined by Stadelmann,[1] shows the general nature of the compound formed when bromine combines with the chromogen:

	A	*D*
C	49.00	48.12
H	5.28	5.09
N	10.99	11.92
S	3.77	3.10
O	11.01	12.00
Br	19.95	19.77

From the average of the several results obtained, it would appear that the proteinochromogen, which could not be isolated by itself in sufficient purity for analysis, must contain approximately 61.02 per cent. of carbon, 6.89 per cent. of hydrogen, 13.68 per cent. of nitrogen, 4.69 per cent. of sulphur, and 13.71 per cent. of oxygen. As a proteid-like body, it is thus especially characterized by an exceedingly high content of carbon and a high content of sulphur. As a product of trypsin-proteolysis, it must presumably come from the cleavage of hemipeptone, which, however, contains only 0.75 per cent. of sulphur. But as we have seen, this latter body breaks down by further cleavage into substances such as leucin, tyrosin, lysin, etc., which contain no sulphur whatever, and as there is no elimination of sulphur in this process through formation of hydrogen sulphide gas or otherwise (putrefaction being excluded by the presence of either chloroform or thymol), it follows that this surplus sulphur must accumulate somewhere. The high content of carbon, however, in proteinochromogen is sufficient evidence that the substance cannot have its origin in a simple cleavage of hemipeptone. On the other hand, everything points to a synthetical process, in which two or more cleavage products of the proteid molecule combine and form a new body, such as proteinochromogen, containing all the sulphur cast off from the hemipeptone in the production of the crystalline bodies, and having in itself properties common to peptone and to a body of the indigo group, the latter obviously coming from some aromatic antecedent.

In view of the apparent complexity of the processes attending trypsin-proteolysis, it is not strange that even simpler substances than those already described should make their appearance. Thus, when it was suggested that ammonia, NH_3, might be formed under the influence of trypsin, it was not considered at all improbable, for in the hydrolytic decomposition of proteids by boiling dilute acid, as well as by baryta water, it had long been known as a prominent product. Obviously, in trypsin proteolysis, the one thing to be guarded against in proving the formation of ammonia is the contaminating influence of bacteria. Hirschler,[1] however, with a full recognition of this danger, made digestions of blood-fibrin with trypsin extending only through four hours and at a temperature of 32° C., and yet obtained plain evidence of the formation of ammonia. Stadelmann,[2] with still greater precautions to exclude all bacterial agencies, using boiled fibrin as the material to be digested and thymol to prevent any possible infection of the digestive mixture, proved conclusively that ammonia was formed as a result of trypsin-proteolysis. Thus, in the digestion of 35 grammes of boiled blood-fibrin with 60 c.c. of a pancreas infusion for three days, 20.8 milligrammes of NH_3 were developed, presumably coming from the liberation of a certain amount of nitrogen attendant upon the formation of such bodies as leucin and tyrosin, which contain considerably less nitrogen than their direct antecedent hemipeptone, or the original proteid. We thus have striking proof of the ability of this peculiar proteolytic enzyme to set in motion hydrolytic changes which may extend even to the production of such simple substances as ammonia, thus making still more striking the parallelism between trypsin-proteolysis, on the one hand, and the artificial hydrolysis produced by boiling dilute acids on the other.

In view of all these facts regarding the nature of the product obtainable by pancreatic proteolysis, it is very evident that many chemical changes may take place side by side in a vigorous pancreatic digestion of proteid matter. We know without a shadow of doubt that all of the bodies enumerated as products of pancreatic digestion are the results of trypsin-proteolysis, and not the products of putrefactive changes. Bacteria, it is true, are able to produce many like products, and in the living intestinal tract exercise an important influence, especially in the breaking down of resistant forms of proteid matter, and in the decomposition of surplus material which has escaped the pancreatic ferment. But all the bodies described above are readily obtainable by trypsin-proteolysis under conditions which exclude all possibility of bacterial action.

Granting, then, as we must, that these various bodies are all products of pancreatic proteolysis when the process is carried on in beakers or flasks, we need to consider next how far such bodies appear in the natural process as it takes place in the living intestine. We know indeed that the natural and the artificial processes are very much alike so far as the qualitative results are concerned, but what differences there may be between the quantitative relationships in the two cases is less certain. One might naturally reason that, with the facilities for rapid absorp-

tion that exist in the small intestine, trypsin-proteolysis would rarely proceed beyond the peptone stage, yet we have ample evidence that, under some circumstances at least, both leucin and tyrosin are formed in considerable quantities in the intestine.

It obviously makes a very great difference to the economy in what form the proteid matter ingested leaves the intestine on its way into the blood-current. It has been more or less generally assumed that, under the ordinary circumstances existent in the intestinal tract, the crystalline and other bodies coming from the more profound changes incidental to trypsin digestion are rarely formed, mainly on the ground that such transformations would entail great loss of nutritive material to the blood. Years ago, Schmidt-Mülheim [1] made a series of experiments on the changes which proteid foods undergo in different portions of the alimentary tract, from which he concluded that leucin and tyrosin are formed in such small quantities in natural pancreatic digestion that they represent only a very small part of the nitrogen absorbed from the intestine. This conclusion has been more or less generally accepted, especially as several observers have reported finding only small amounts of these bodies in the intestine under what might be assumed to be favorable circumstances for their formation. In artificial digestions, on the other hand, as we have seen, leucin and tyrosin, together with the other simple bodies described, may appear in large quantities. Obviously, two suggestions present themselves as explanatory of this difference: either there is such a rapid absorption of these crystalline products from the intestine that they cannot be detected other than as mere traces, or else the natural process takes a different course from the artificial, owing to the rapid withdrawal from the intestine of the antecedent of the leucin and tyrosin, viz., the hemipeptone.

Concerning this point, Lea [2] has recently reported some experimental evidence obtained by a comparative study of artificial pancreatic digestion as carried on in a flask, with similar digestions carried on in parchment dialyzer tubes, the latter so arranged that the diffusible products of proteolysis can pass from the tube into the surrounding fluid. As Lea justly says, this whole question of the formation of leucin by proteolysis is a very important one, since it bears closely upon one of the possible methods by which urea may be quickly formed from proteid food. Thus, we have evidence that when leucin is administered to mammals a portion of its nitrogen, at least, quickly reappears as urea and uric acid in the urine.[3] Further, there is a certain amount of evidence that this transformation takes place in the liver, viz., in the organ where leucin absorbed from the intestine would naturally be first carried.[4]

Obviously, the main point to be gained in a dialyzer experiment is the removal of the soluble products of digestion as soon as they are formed; but peptones are not rapidly diffusible, and the process, as noted under the head of gastric digestion, cannot be considered in any sense as yielding the same results as might be obtained in the living intestine. Still, the method offers a closer approach to the natural process than when carried on in a flask, and the results are of interest. Thus, Lea finds in the first place that in a dialyzer-digestion the proteid is more quickly dissolved, and that there is far less tendency for the formation of an insoluble antialbumid with its natural resistance to the ferment. Still, it is to be noticed that the amount of this antialbumid residue formed by trypsin-proteolysis in a flask is mainly dependent upon the strength of the ferment solution and the character of the proteid undergoing digestion. If the latter is in a fairly digestible form, and the enzyme solution reasonably active, then even the flask-digestion may show almost no residue of antialbumid. Yet there is at least a shade of difference in the two cases, which may be expressed by the statement that trypsin-proteolysis, as carried on in a dialyzer tube, is prone to give less insoluble antialbumid than a corresponding digestion in a flask. Further, the amount of leucin and tyrosin formed in a flask-digestion is always greater than in a dialyzer digestion, other conditions being equal. Naturally, these results help us very little in drawing any conclusions regarding the extent to which leucin and tyrosin may be formed in the intestine. They merely emphasize the fact that the withdrawal of a certain quantity of hemipeptone from the digestive mixture tends to reduce by so much the yield of leucin and tyrosin. It is hardly to be assumed, however, that the rate of withdrawal of peptone from the intestine can keep pace with its formation, especially when it is remembered that the proteid matter coming into the small intestine, owing to its preliminary treatment in the stomach, is in a comparatively digestible condition. Further, the pancreatic juice is a remarkably active fluid, and proteolysis under its influence must make rapid strides. I can easily conceive that proteolysis by trypsin, when carried on in a flask, may lead to the formation of much larger amounts of leucin and tyrosin, and of other bodies as well, than occurs in the natural process; but there is certainly no ground for the belief that leucin and tyrosin are wholly wanting in pancreatic proteolysis as it occurs in the intestine.

With a view to obtaining some positive evidence on this point I have tried a few experiments on animals, the results of which have convinced me that, in the case of dogs at least, both leucin and tyrosin may be formed in natural pancreatic digestion in considerable quantities. Thus, in one experiment a good sized dog, kept without food for two days, was fed four hundred grains of chopped lean beef at 8 A.M. At 2 P.M. the animal was killed and the intestine ligatured close to the pylorus. The lower end of the small intestine was likewise ligatured. The portion inclosed between the two ligatures was then removed from the body and the contents of the intestine pressed and rinsed out with distilled water. In the stomach was found a small amount of semi-digested matter weighing about fifty grammes. The material obtained from the intestine was strained through mull, the fluid rendered faintly acid with acetic acid, and heated to boiling. The clear filtrate from this precipitate was concentrated to a very small volume, and while still hot precipitated with a large amount of ninety-five per cent. alcohol. A small gummy precipitate resulted, which was thoroughly extracted with boiling alcohol and the washings added to the alcoholic filtrate. The precipitate contained some deuteroproteose and a small amount of true peptone.

The alcoholic fluids were evaporated to a small volume and set aside in a cool place. As a result, quite a separation of leucin and tyrosin occurred in the characteristic cystalline forms. No attempt was made to effect a quantitative separation of the two bodies, but the mixed precipitate finally obtained weighed, after recrystallization, over three fourths of a gramme. Leucin was plainly in excess, but considerable tyrosin must have been left in the alcoholic precipitate, owing to its greater insolubility in this menstruum. This experiment is almost a counterpart of one reported by Lea,[1] and like his indicates that both leucin and tyrosin may be formed in not inconsiderable quantities by pancreatic proteolysis as it occurs in the intestine. This being so, one is naturally called on to explain "the physiological significance of a process which at first sight appears to result in a degradation of the potential energy of proteids, under conditions such that the energy set free can be of little use to the economy." [2] But it is quite possible, as Lea has suggested, that these amido bodies have an important part to play in some of the synthetical or other processes of the organism, and that their formation is consequently necessary for the well-being of the body. Whether this is so or not, we

may well consider the formation of these amido-acids in pancreatic proteolysis as a means of quickly ridding the body of any excess of ingested proteid food, with the least possible expenditure of energy on the part of the system. This has always seemed to me the probable purpose of the profound changes which the pancreatic ferment is capable of inducing.

The primary object of both gastric and pancreatic proteolysis is to render the proteid foods more easily available for the needs of the economy, viz., to aid in their absorption and consequent distribution to the master tissues and organs of the body. This is doubtless fully accomplished by the formation of the so-called primary and secondary products of proteolysis, *i.e.*, the proteoses and peptones which are, comparatively, not far removed from the mother-proteid, except in solubility and other minor points. In the ferment trypsin, however, we have a special agent endowed with the power of carrying on the hydrolytic cleavage to a point where exceedingly simple bodies result, and through whose agency any excess of proteid material in the intestinal canal may be quickly broken down into a row of products easily removed from the system. It is to be remembered, however, that the very nature of the proteid molecule precludes the possibility of anything like a complete decomposition into crystalline or other simple products. Full fifty per cent. of the peptone formed must be antipeptone, which cannot be further changed by trypsin under any circumstances, so that, whether the amount of proteid in the intestine be large or small, or whether it is exposed for a longer or shorter period to trypsin proteolysis, there will always be a fairly large amount for absorption. This may well be considered as one of the reasons for the peculiar structure of the proteid molecule, the anti group being always available for the direct nutrition of the body, while the representatives of the hemi group, especially when proteid is present in excess, can be quickly and readily broken down into simple products. In other words, the direct formation of these simple bodies in the intestine furnishes a short path to urea, thus leading to the rapid elimination of any excess of proteid material.

We may well attribute to the epithelial cells of the intestine the power, under normal circumstances, of regulating and controlling, even though indirectly, the order of events in the intestine. Just as the so called secreting cells of the tubuli uriniferi may lose for a time their power to pick out from the blood material destined for the urine, being clogged or exhausted by continued effort, so the epithelial cells of the intestine, which play such an important part in the absorption of proteid matters from the alimentary tract, may, in the presence of an excess of proteid matter, become temporarily exhausted, and, refusing passage to the proteoses and peptone formed by proteolysis, render possible further hydrolytic cleavage into leucin, tyrosin, lysatin, etc.; bodies which, by one method or another, can be readily transformed into urea. At the same time, as already stated, it seems more than probable that some formation of these amido-acids always occurs in the intestine, and that these bodies have some specific part to play in the normal processes of metabolism going on in the body. The more one studies the processes of nutrition in general, the more one is impressed with the view that there is a purpose in everything, and that the formation of even such bodies as leucin and tyrosin may be connected with hidden processes, the key to which has not yet been found. We see an analogous case, perhaps, in the action of the inorganic salts in nutrition, some of which, at least, neither undergo change themselves nor induce changes in the substances, and yet we know their presence is indispensable for keeping up the normal rhythm of the nutritional process of the body.

SOME FACTS BEARING ON THE ETIOLOGY OF TYPHOID FEVER.

By CYRUS EDSON, M.D.,

COMMISSIONER OF HEALTH FOR CITY AND STATE OF NEW YORK.

Typhoid fever, as is well known, is particularly prevalent in the fall and in the spring of the year. It is also significant that many of the great epidemics of typhoid, which have been transmitted through the medium of water-supplies of towns, have been caused by infection occurring during the winter months. In the case of the epidemic that broke out in Plymouth, Penn., a few years ago, the infective material was deposited on the banks of a small stream on the snow, then several feet deep, where it was subjected for a number of days to a temperature of about twenty degrees below zero. A thaw occurring, it was washed into the stream and thence into the water-supply of the town. From twenty to twenty-five days later, a large number of persons in the town were taken sick with typhoid fever.

A very interesting outbreak of typhoid fever has recently occurred in the town of Grand Forks, N. Dak. I am indebted to Mr. W. S. Russell, City Engineer of Grand Forks, for the following facts: The town of Grand Forks is situated on a tributary of the Red River of the North. Its population is about ten thousand. Its water supply is taken from the stream on which it is situated, at a point well above its sewage discharge, which is also into the stream. Sixty miles above Grand Forks is the town of Crookston, with a population of about four thousand. Just prior to November 17, 1893, several cases of typhoid occurred in the latter place, and, as a precautionary measure, the sewers of Crookston and a number of cesspools were thoroughly flushed out with water, causing a discharge into the river of a large body of contaminated water. The river at the time was coated with thin ice. This flushing was done on November 17, 1893. About thirty days later (approximately the period of incubation of typhoid fever, plus the time elapsed for the infection to flow sixty miles) typhoid fever broke out in Grand Forks, and between December 17, 1893, and March 1, 1894, one thousand one hundred and sixty-nine cases occurred in the town. The mortality was exceedingly low, however, only seventy-eight deaths being reported.

We have recently had another example of winter typhoid, that afforded by the city of Buffalo, the details of which, however, are not at present available. Numerous other examples of typhoid occurring during the winter, the early spring, and the late fall, could be instanced, and it seems to the writer that these outbreaks point definitely to the fact that the infection of typhoid fever is much more dangerous during the cold weather, when the temperature of the water is near the freezing point, than at any other time.

Two causes probably operate to effect this: First, oxidization, due to the action of free oxygen and resultant oxidizing processes in the water, affects organic compounds, and destroys germ life more rapidly under the influence of warm weather; second, the micro-organisms of fermentative decomposition of organic matter (including the nitrifying bacteria) in contaminated water are most active when the waters are warm, and these germs or their products are probably inimical to the bacillus typhosus. Cold water, in other words, tends to hold the typhoid bacillus unchanged; to preserve it so that it may be carried great distances by flowing streams, and to render the contamination of the underground currents supplying wells and springs much more dangerous during the cold seasons of the year than in the summer, when oxidation and fermentative changes due to warmth are active.

The Board of Health directed its bacteriologists to make weekly bacteriological examinations of the Croton

water during the year 1893, for the purpose of determining the number of bacteria per cubic centimetre capable of growing in nutrient gelatin at room temperature. This was regularly done under the supervision of Dr. Hermann M. Biggs, Director of the Bacteriological Laboratory. A study of the results obtained is of very great interest, and bears directly on the subject under consideration. The following table shows the average per month of the number of bacteria per cubic centimetre:

January	6,828	July	302
February	5,202	August	394
March	3,122	September	429
April	1,180	October	527
May	1,078	November	705
June	392	December	10,465

The following table shows the average number of bacteria in one cubic centimetre. This has been compiled in order to show conditions during the cold months:

January, February, and March	5,051
April, May, and June	883
July, August, and September	375
October, November, and December	3,872

Mr. Alfred L. Beebe, of the Board of Health Bacteriological Laboratory, in his report analyzes these figures as follows: "It will be noted, first, that there is a steady decrease in the number of bacteria for the first seven months of the year, and a corresponding increase in the remaining five; second, that the number of bacteria is much higher during the colder than during the warmer months (average for January to March, and October to December, inclusive, 4,962; for April to September, inclusive, 629); third, that in nearly every case where the number of bacteria on a given date is abnormally large as compared with that for previous and succeeding dates, a rainfall and the putting into use of a new storage reservoir was, on investigation, found to have taken place some days previous; fourth, that the number of bacteria is very much greater during the months when the ground is frozen than that of the rest of the year (average for January, February, March, and December, inclusive, 6,404; for April to November, inclusive, 626). This latter fact can probably be partly accounted for by the increase of surface wash from rainfall when the ground is frozen, which carries with it into the various water-courses large numbers of soil bacteria." But it is to be partially accounted for because of the facts which I have already given, viz., decreased effect of oxidization in the presence of low temperature.

"The regular decrease in bacteria from January to July, and the corresponding increase from the latter date to the end of the year, are curious, and at first sight apparently exactly the reverse of what would be expected. It has usually been supposed that water contamination was much more dangerous during warm weather, when the heat favored germ propagation. As the average temperature rises during the year, and all forms of vegetable life exhibit increased activity and abundance, it would seem that the bacteria in water should follow the general rule." That the reverse is true finds its explanation in part at least to increased oxidization in summer under effect of heat, to which I have called attention.

The subject may be summed up, to wit: *Experience and science point straight to the fact that water purifies itself much more efficiently and with greater rapidity in warm than in cold weather.*

Flies and the Transmission of Disease.—During the epidemic of cholera at Hamburg, Dr. N. Simmonds examined flies captured in the post-mortem room at the time the bodies were open. In these flies numerous comma bacilli could be demonstrated. When the autopsies were concluded and the room washed, the cholera bacilli could not be found. An attempt was made to find how long the cholera germs were retained by the insects, and it was found that they disappeared in one hour and a half.

THE EYE-TREATMENT OF CHOREA.

A Critical Review of Certain Factors that may Lead to Spasmodic Diseases, and the Treatment of such Conditions without Drugs.

By AMBROSE L. RANNEY, A.M., M.D.,

NEW YORK.

My attention has been attracted by a most remarkable statement that has lately appeared, viz., the following quotation from a brochure, by an author of repute,[1] that has been published relative to the causation of chorea. He says: "The more recent studies of the pathology of chorea have led to a practically *unanimous*[2] conclusion that the seed of the disease is primarily in the blood-vessels and the blood, with secondary degenerative changes in the parenchyma, and that the cause is either some microbe or toxic substance, or both."

If such a conclusion be as nearly unanimous among the leading neurologists and pathologists as this author would assume, the following cases will, perhaps, prove food for their further reflection, and possibly a basis for the development of some new hypothetical theory relative to the satisfactory results that have been obtained by eye-treatment alone.

It is certainly inconsistent with any such visionary theory (although based upon the results of pathological and bacteriological investigation), that many cases of the most aggravated and chronic type of chorea should get well without recourse to drugs; and remain free from any return of the spasmodic movements of the face, trunk, or limbs, whenever sources of peripheral reflex irritation are scientifically investigated and satisfactorily corrected.

If it can be shown (as it has already been to the satisfaction of many) that a thorough relief from eye-strain has alone produced a complete and permanent cure of many cases of chorea that were chronic and apparently hopeless, I doubt if the majority of intelligent practitioners of medicine will concur in the belief that purely local treatment (confined to the muscles of the orbit and the refraction of the eyes) effected such results through elimination of microbes or by neutralizing toxic materials.

It was not long ago that a few enthusiastic pathologists became strongly imbued with the belief that some intestinal poison was to be discovered as the cause of epilepsy—a theory that, to my view, has not to-day the support of the best minds in the profession. It utterly fails to explain the published results obtained by me in twenty-five aggravated cases of that disease, treated exclusively through the eyes,[3] as well as similar cases that have been reported by others.

Neither has the theory that a rheumatic diathesis creates chorea, which was for a long time highly extolled, any practical bearing upon the relief of choreic symptoms in the vast majority of the cases of chronic chorea that are encountered. At the present day, as in decades past, the physician continues to treat choreic symptoms with arsenic, as about the only drug that seems to control them. The changes are rung, from time to time, in very obstinate cases, by incorporating with arsenic tonics, strychnia, cold packs, cod-liver oil, chloral, morphia, picrotoxin, cimicifuga, antifebrin, salol, various electrical currents, experiments with magnets, and such other steps as the medical attendant (in his dire extremity) deems best suited to the exigencies of the case.

Some choreic patients seem for a time to recover under each of the various forms of medication suggested.[4] Some get well only when all of the drugs mentioned have been withdrawn; but a few continue to exhibit their spasmodic contortions in aggravated forms, until.

[1] American Journal of the Medical Sciences, January, 1894.

[2] Italics my own.

[3] New York Medical Journal, January 12, 1894. In this brochure I have given in full the various steps taken during the treatment of each case. The reader is referred to this contribution for many points that bear upon the diagnosis and correction of heterophoria.

[4] There is scarcely a drug in the Materia Medica that has not been at some time employed with apparent benefit in the treatment of chorea.

wearied with attempts to obtain relief, they resign themselves to fate, or in their despair are led to search for sources of reflex irritation.

We are all exposed (from birth until death) to the presence of certain atmospheric germs or microbes. Many forms of these are constantly being introduced into our bodies through the air, our food, and the water we drink. Constantly, through life, are certain toxic materials also being formed within the human body and eliminated through the kidneys, liver, intestinal tract, etc.

In some subjects, when the most favorable conditions for their retention, absorption, and multiplication exist, do these microbes and toxic substances hasten the dissolution of life; while in others that possess a reactive power capable of combating the elements of disease, life goes on in spite of microbes with its normal growth and decay.

We are forced to admit that seeds sown by the farmer as well as those of the weed carried and distributed by the wind flourish best in soil that is properly prepared for their reception and development. Is it therefore irrational to assert that any of the underlying causes of nervous debility, any constant sources of excessive and unnatural nervous expenditure, any hereditary condition that creates an uninterrupted leakage of nerve-force, may be an important factor in fitting the human soil for the seeds of disease that are ever present and ready to take root?

Should investigation end whenever microbes or toxic materials are discovered in the human economy? Should the causes of a diseased condition be regarded as determined so long as the underlying factors that enable this cause to exist and flourish are ignored? Which is the most important in medicine—to ascertain what adventitious agent can do damage under favorable conditions, or to so improve the nervous power of a patient as to enable the body to resist the seeds of disease?

So long as we are incapable of fighting our foe (when once established with a firm foothold within the human economy), what have we gained from the standpoint of the sufferer by simply knowing the name, exact appearance, or seat of the enemy?

I would not be construed as decrying the scientific results obtained by careful, painstaking bacteriological or pathological research. They undoubtedly tend to furnish the medical practitioner with some knowledge, after the chaff has been eliminated and the wheat carefully collected, that may in time aid in the prevention of disease, and possibly facilitate its cure. But, while these investigations are going on, while with great rapidity theories are being hatched and exploded, while the views of to-day may not be those of to-morrow, is it not the duty of every earnest practitioner of medicine to listen with attention to clinical facts that are capable of absolute verification, that are often fraught with immediate results to suffering humanity, and that open a wide field for the treatment and relief of obscure nervous diseases?

With these few preliminary remarks, I approach the discussion of certain factors in the causation of chorea that I believe to be vitally important. I shall endeavor to demonstrate the accuracy of these views by the details of treatment of several illustrative cases of extreme and chronic chorea.

In the first place, I would assert (as I have often done prior to this date) that clinical experience has demonstrated most positively a *direct causal relationship between eye-strain and chorea.*

The forms of defect encountered in the orbit, and their degree, are (in a very large proportion of chronic and transient cases of chorea) such as to entail upon the sufferer an enormous expenditure of nerve-force that is not only unnatural and detrimental to health, but capable of arrest by skilful hands.

This assertion is not a new one. It has been made over and over again during the past decade by many oculists of repute. It is a statement that can easily be verified by anyone who practises the later methods of investigating refraction or anomalies of adjustment of the muscles of the orbit (heterophoria);[1] yet it is one that is to-day too commonly ignored by many neurologists. Some seem to be too deeply engrossed in hunting for obscure causes of disease to see those that are already demonstrated; while others apparently prefer to accept any visionary theory rather than a plain clinical fact, if that fact tends to relegate drugs to the background.

To anyone who delves in the medical literature of the past, and who reads the theories that have flourished and been forgotten, it becomes at once apparent that the tendency of this age is to seek for the causes of disease, and, as far as possible, to remove them.

The argument that is advanced here is no longer a theory. It is supported by well-established physical laws and sustained by physiology. Furthermore, the results obtained when the abnormal eye-factors have been scientifically determined and removed can be shown to be almost instantaneous, and somewhat startling, in many of the cases thus treated.

Two years ago, one of the leading medical journals of this country published in its editorial pages,[2] in strong advocacy of this method of treatment, several columns under the following heading: "A Great Medical Discovery Ignored." From this editorial I quote the following paragraphs:

"There are few medical truths that have been discovered fraught with more possible and incalculable good to humanity than one that is ignored by the great body of the medical profession.

"There are explanations and sufficient reasons for this anomalous fact. Among them may be noted these:

"1. The discovery has come about slowly and silently. It has been made by no one man, and has come with no flourish of international congressional trumpeters. So softly and slowly has it crept into scientific medicine that its own advocates are but half aware of it, and do not yet realize its almost unparalleled value.

"2. It is a therapeutic measure that depends for its exercise upon an exactness of knowledge of delicate, mysterious physiological and psychological functions that few possess, and upon a subtle discrimination and judgment with which, by character or education, few are endowed.

"3. It has the misfortune to depend for its promulgation and practical application upon the specialist, and almost upon the specialist of a specialty—and this in a profession and in an epoch in which it is fashionable to sneer at specialism, and at the specialist who dares plead for the truth he knows—and that, at first at least, only he can know."

Perhaps the most common experience that I personally encounter in my office is to have patients tell me that either their doctor or some oculist whom they have consulted has said to them that "their eye trouble is the *result* of their physical weakness and *not a cause; that the relief of the eye trouble can have nothing to do with their recovery;* and that all statements to the contrary are not supported by facts."

It is for the purpose of demonstrating the counter-proposition, of showing that "eye-strain" may indirectly be the *cause* of obscure disease and not its result, and of turning, if possible, the channel of medical thought so as to benefit suffering humanity, that I deem it wise to raise my voice again in defence of a method of treatment that will often accomplish what drugs will not, and that is based upon science rather than therapeutical speculation and empiricism.

The few cases of chorea which I report here in detail I have selected from a number on my private records, in order to demonstrate most positively my view of the points at issue. They have been seen by many physi-

[1] The terms now commonly employed to designate anomalies of adjustment of the muscles that move the eyes were first suggested by my friend, Dr. George T. Stevens. They include the following: *Heterophoria*, abnormal deviating tendencies in any direction; *esophoria*, a tendency to deviate toward the nose; *exophoria*, a tendency to deviate toward the temple; *hyperphoria*, a tendency of one eye to seek a higher plane than its fellow; *orthophoria*, a normal condition of the eyes in respect to equilibrium.

[2] Medical News, December 12, 1891.

cians from time to time. To many of these patients the verbal or written opinion of prominent medical men had been given prior to my seeing them, "that *organic disease* unquestionably existed, and that the eyes had nothing to do with the causation of the symptoms."

In some of these cases no possible explanation of the facts here recorded can be suggested, except to admit that the correction of an existing "eye-strain" caused a cessation of the leakage of nervous force that had been going on for years; and, by so doing, the sufferers had been enabled to regain their normal condition.

The sad results, viewed from the standpoint of suffering humanity, that are entailed by indifference and prejudice in men of scientific reputation cannot be estimated.

By giving expression to others of their opinion concerning what they have not properly and patiently investigated themselves or will not see, thousands of sufferers are doomed to a life of misery.

Such patients naturally believe that abnormal eye-factors in their own case have been sought for by the latest methods and found to be absent by one who stands high in his profession. They quote to their friends the positive assertions of him (whom they believe infallible), that "eye-muscles are not worth investigating;" that "all deviating tendencies of the eyes are invariably due to errors of refraction;" that "Javal's instrument has been used, and that settles the question forever;" and other similar expressions, indicative either of inexperience, bigotry, or prejudice, that too often come to my own ears.

We are now prepared to pass to the consideration of some cases of chorea that I have selected from my case-books in order to demonstrate, if possible, beyond cavil that a direct relationship between "eye-strain" and extreme forms of nervous disturbances can exist; that the correction of "eye strain" may be followed by very marked benefit in some instances; that it is the duty of a physician to have the eyes of all patients afflicted with abnormal nervous disturbances examined early by some oculist who is familiar with and employs the latest methods; and that errors of adjustment of the eye-muscles are quite as important to detect and rectify as are marked errors of refraction.

Respecting the *relationship of chorea to anomalies of the visual apparatus*, I am led by my experience to draw the following conclusions:

1. Choreic subjects belong to one of two classes: (*a*) Those who tend to get well under almost any treatment, or even without treatment, and (*b*) those who fail to get relief from any medicinal aid. The latter tend to run a chronic course, usually one of unfavorable progression.

2. The *chronic form of chorea is one of the most serious and hopeless of nervous maladies* when treated by drugs alone. It is not infrequently associated with epilepsy or with mental impairment later in life. Chronic sick-headache may often be developed; and sometimes asthenopic symptoms are quite prominent.

3. Both forms of chorea are based, as a rule, upon a well-marked *neuropathic* or *tubercular predisposition*.

4. The pathology of chorea is not known. No one has ever proved that it was a "constitutional disease," in the sense that an organic lesion was essential to its development.

5. The *percentage of hypermetropia (usually latent) in choreic subjects is extremely large (apparently about seventy per cent)*. I make it a rule, with few exceptions, to correct the total error of refraction in choreic subjects fully by glasses. Often atropine has to be instilled into the eyes at frequent intervals, for a time, in order to arrest ciliary spasm, and enable the patient to accept a full refractive correction without marked discomfort.

6. The glasses ordered for choreic patients should be *most carefully fitted to the face* and *accurately centred to the pupils*.

7. An *investigation* for *latent heterophoria*[1] should always be made in choreic subjects with the greatest of care and patience.

8. The *relief* of *marked heterophoria* should be finally attained only by *graduated tenotomies* upon the muscles exhibiting abnormal tension, or by an *advancement of the tendons of the muscles exhibiting defective power*.

9. *Prismatic glasses are not curative*. They should not, as a rule, be prescribed for constant use.

10. Choreic subjects are usually rapidly cured by eye-treatment alone. So large has been the percentage of recoveries to the total number seen by me during the past ten years, that I have come to regard the prognosis of chronic chorea as extremely favorable.

11. The eye-problems encountered in choreic subjects are not, as a rule, as complicated and difficult to solve as those of epileptics; nor, in my experience, is the duration of eye-treatment apt to extend over as long a period before very decided benefit is observed.

12. I believe that the spasmodic movements which accompany and indicate organic lesions of the brain, as, for example, those of a lepto-meningitis, exist in but a small proportion of choreic subjects, and are usually associated with other evidences of disease.

That organic lesions of the brain and spinal cord may produce choreic movements of an extreme type, cannot be denied; but it is wise, in my experience, to be slow in giving an unfavorable prognosis in any case until all possible reflex causes of chorea have been thoroughly investigated and corrected.

13. The removal of young choreic subjects from school, or of adult choreic patients from business, is a step commonly taken by most physicians while treating chorea by drugs.

It must be apparent to all thinking minds that the rest thus given to the eyes and nerve-centres is a factor in the recovery of acute cases of chorea that is as important clinically as the drugs employed.

CASE I. *Aggravated Chorea, with Impairment of Speech and Walking.*—Miss L——, aged fifteen. Referred to me July 5, 1893, by Dr. Symmes, of Cranberry, N. J.

Family History.—The mother has always had violent sick head aches. One maternal aunt has severe sick-headaches. No phthisis in the ancestry.

History of the Case.—The patient has had marked chorea, off and on, for the past eight years. The first attack followed inflammatory rheumatism; but she has had no evidence of rheumatism since that attack.

About two months before I first saw her, she began to have pain in her eyes and sensitiveness to light. This was followed by the worst attack of chorea that she has ever had.

The twitching of legs, arms, and face was very marked, and her speech was so thick as to be almost unintelligible.

She walked with great difficulty, being unable to control her limbs.

During her first visit to the office she tore a handerkerchief into threads. She twitched so violently that her head had to be held by main force during the eye-tests; while her arms and legs were going in all directions She had slept very poorly for several weeks.

Eye Defects.—At the first examination the patient showed: Adduction, 33°; abduction, 7°; no hyperphoria; esophoria, 15°; in accommodation, esophoria, 10°; homonymous diplopia with a red glass, under homatropine, hypermetropia (+0.50^s) and astigmatism (+0.50^c axis 90°) in each eye.

After wearing a 5° esophoria prism for a short time, she showed esophoria of 22° and abduction of 2°.

Treatment and Results.—A full correction was given for her refractive error both for reading and distance. Graduated tenotomies were performed on the internal recti; one on the right internus and two on the left internus. Her tests two weeks after the last operation were: adduction, 47°; abduction, 8°; no hyperphoria; esophoria, 1°; vision, $\frac{20}{15}$ in each eye with refractive correction.

[1] A term that covers all forms of mal-adjustment of the muscles of the orbit.

Two days after the first operation, the patient's mother reported that she had slept through two entire nights very quietly. After the second operation, she appeared much more quiet and continued to sleep well.

Two weeks after the last operation and five weeks after the first visit, her mother reported that the patient was "absolutely well of all choreic symptoms."

A letter from her pastor dated October 6, 1893, says: "You ask what I think of Miss L——'s improvement. It is little short of miraculous. Both she and her parents owe you a debt that no money can discharge. When I see her now and consider her condition three months ago, my heart goes out in thankfulness to God that he has given unto men wisdom and power to so relieve the sufferings of mankind."

Up to the writing of this brochure, a report states that no return of the chorea has been observed, and that the patient continues to exhibit perfect health.

The complete and rapid recovery of this girl was naturally a source of great surprise to everyone who knew her. Her defective articulation and extreme chorea justified alarm, and a strong suspicion that some organic disease had been developed, of which the chorea was but one manifestation.

The following case is one of the most remarkable ones that I have ever seen. There was every reason to think that an organic lesion of the brain existed. I could hardly believe at first that marked benefit from eye treatment was to be expected.

Case II. *Chronic Chorea Followed by a Loss of Power in both Legs and the Right Arm.*—Miss S——, aged ten, a large child for her age, sent to me for treatment on June 15, 1891.

Family History.—Mother is perfectly well. Father has had some eye-trouble. One cousin on maternal side had epilepsy. One maternal aunt has nervous prostration. Paternal grandmother had nervous prostration. Considerable phthisis in the father's family.

History of the Case.—The patient has had several severe sicknesses from acute diseases incident to childhood.

Eight months ago it was noticed that she could not keep her hands still, and was constantly knocking things over. This kept growing worse until, six weeks before she came to me, she lost all use of the right hand. Her ankles, which had been growing weak for some time, turned over so badly that she occasionally fell down. At times her speech was badly affected, and her words often ran together so as to be almost unintelligible. When she reads, the letters blur badly and her eyes become very much inflamed. Her eyes had troubled her for some time before any choreic symptoms were noticed. One eminent neurologist of this city had seen the patient and pronounced the case one of organic brain disease. He had given a very unfavorable prognosis.

Eye Defects —Latent hypermetropia, + 1.00 s. Esophoria, 8°. Adduction, 38°. Abduction, 2°. Right sursumduction, 2°. Left sursumduction, 2°. A high degree of latent esophoria was subsequently disclosed by this patient.

Treatment and Results.—The treatment consisted in giving prisms, bases out, over each eye for constant wear, and later in performing graduated tenotomies upon both internal recti.

The improvement in the choreic symptoms began almost as soon as the prisms were put on. At the end of the first week her mother reported that she could dress herself much better than formerly; that her right hand rested quietly in her own when walking, whereas it used to be impossible to hold it on account of the twitching. She also began to use her right hand for the first time while in my consultation-room, to denote the position of test-objects while her eye-muscles were being tested.

The patient, four months after treatment was begun, wrote and sewed with her right hand, walked perfectly well, without turning of the ankles, and had no choreic symptoms whatever. The power in her right arm was fully regained later. The parents state that "she is as well as she ever was," and express the greatest gratitude because of her restoration to health. For nearly three years no return of her choreic symptoms has been observed.

On January 19, 1894, a friend of the parents of this patient visited the office. He reported that "the patient was now a strong and robust young lady, and that she had never at any time had the slightest symptom of her old trouble."

The third case reported had been regarded as a medical puzzle by most of the physicians that had been called upon to examine her. She had been totally incapacitated for work for four years, and no benefits from drugs had been obtained.

Case III. *Aggravated Type of Chronic Chorea, Accompanied by Deformity, Headache, Asthenopia, and Inability to Work.*—Miss C——, aged twenty-six, single. Referred to me for diagnosis February 27, 1888.

Family History.—Not known.

History of the Case.—The patient was a poor factory girl that was sent to me by a medical friend, Dr. O'Connor, of Holyoke, Mass., to see if anything could be done for her. No one who had seen her could make a diagnosis, although she had been seen by most of the prominent physicians of the State. Since her tenth year she had suffered with neuralgic headaches, asthenopia, and persistent trembling in her hands and arms. For four years there had been a stiffness and rigidity of the neck, accompanied by severe pain in the neck and "choking spells" when she attempts to speak or when excited. There is also marked contracture of the hands and arms.

Her appearance when she came to me was one of remarkable deformity. Her chin seemed to be held firmly in the region of the chest at the level of the fourth button of her dress. Both upper limbs were contractured in the state of semiflexion at elbows, wrists, and fingers, and trembled excessively when she tried to use them. They could not be extended, nor could the patient make use of the hands. She had been obliged to give up work on that account. Whenever she talked her face became painfully drawn and distorted. The mouth would especially be drawn downward. Under the least excitement she would be seized with what she called "choking spells." The throat muscles would contract and interfere seriously with respiration. She had constant headache, chiefly in the forehead and occiput, and a persistent pain in the neck. No painful points existed, nor did pressure, movement, or other tests reveal the existence of organic disease of the spinal cord. Sensibility to touch, pain, and temperature was normal. Motility was unimpaired. The muscular sense was perfect. No incoordination existed. I considered the case one of aggravated chorea, complicated by headache and asthenopia.

Eye Defects.—Hypermetropia, + 0.75. Esophoria, 20° (mostly latent). Left hyperphoria, 3°. Adduction, 22°. Abduction, 5°. Right sursumduction, 2°. Left sursumduction, 5°.

Treatment and Results.—The muscular anomalies were satisfactorily relieved by graduated tenotomies of both internal recti and the left superior rectus. Applications of static sparks were made daily for about two months. The patient had by this time regained the use of both hands, carried her head erect, had no headaches, and little spinal pain. For a while she returned to work. The effect of hard labor brought back her "choking spells;" hence she was advised to take absolute rest if they continued. She now has some asthenopia remaining and an occasional headache. Her facial contortions persist to a slight extent when she is unduly excited; but otherwise no spasmodic movements are noticed. I suspect that some latent hyperphoria exists still, and that further operative work on the eye-muscles will be demanded before the patient recovers completely.

The last report from this patient stated that there was a steady improvement in her condition, and that she had again returned to work. She had no headache and few

"choking spells." Her head and hands were no longer affected with distortion.

The following remarkable case is quoted from my work on "Nervous Diseases."[1] This patient was seen by me in the office of my friend, Dr. George T. Stevens.

CASE IV. *Chronic Chorea of Twelve Years' Duration with Horrible Facial Contractions.*—Mr. C——, minister of the gospel. Mother died of phthisis.

Family History.—No nervous diseases had existed among his direct ancestors, or in remote branches of his family.

History of Case.—About twelve years before this interview, his family had noticed frequent facial contortions which he was unable to control. A trip to Europe, and parish labors in a district where he spent most of his time in a carriage and wrote but little in his study, prevented its increase for about four years. He then became the pastor of a church and began active labor in his study. The facial contortions grew rapidly more aggravated in character. Every feature would become horribly distorted; the eyes would close, the forehead become terribly wrinkled, and the nose and mouth would assume attitudes which no one could possibly imitate by volition, and which it is difficult to describe. The hour of retiring was particularly dreaded, because the facial spasms would become terribly persistent and severe as soon as the eyes were closed and a recumbent posture was assumed. The facial contortions were always least severe in the morning, and grew more severe as the day progressed. No medicinal treatment had ever benefited the patient.

Eye Defects.—An examination showed hyperopia of a high degree, esophoria of 6°, and hyperphoria of right eye of 3°. He had been wearing *prisms with the base inward*, at the suggestion of an oculist. Naturally, he had been made decidedly worse by their use.

Treatment and Results.—A partial tenotomy was first performed to correct the hyperphoria. The facial spasms *ceased within an hour;* and no *sign of chorea was observed for two entire days.*

On the third day a very slight twitching about the mouth developed. A partial tenotomy of the internal rectus of the left eye was then performed. This completely corrected the esophoria.

Subsequent to the second operation, the patient had few, if any, choreic movements. He stated to me that, "unless excited, his face remained absolutely quiet," and that for the first time "he had that day been able to attend a meeting of ministers and look them in the face without facial spasms while discussing church matters." During his recital of his various symptoms, etc., to me, his face only showed one very slight convulsive movement. Thus, in less than one week, were the convulsive spasms of his face almost completely arrested by correcting a hyperopia and two muscular defects associated with the eye.

Such a case is rarely encountered. The patient was an adult. The duration had exceeded twelve years. The spasmodic movements were terribly severe. All medication had failed even to ameliorate them. They became greatly aggravated as soon as the patient was compelled to use his eyes in study or writing. He could not even "look out of a car window" without being thrown into a most distressing state; yet, in spite of all these unfavorable facts, he was apparently perfectly well when I last conversed with him.

CASE V. *Extreme Chorea of Face, Arms, and Legs.*—Miss H——, aged fifteen, referred to me August 17, 1889, by Dr. G. B. Banks, of Huntington, L. I.

Family History.—The mother has very severe headaches. One brother has sick-headaches. One sister had phthisis.

History of the Case.—The patient had been perfectly well until she had pneumonia, eighteen months prior to her visit to my office. About six months prior to the first examination by me she began to have twitchings in her hands and arms. These grew gradually worse, until at the present time they affect her legs, arms, and face to a marked degree. She frequently drops whatever happens to be in her hands, her mouth twitches very badly, and she is extremely nervous and excitable. She had some asthenopic symptoms four years ago, but has not been troubled since with her eyes. She is also troubled with marked dyspnœa on the slightest exertion.

Eye Defects.—Under atropine the patient showed: hypermetropia, + 0.75[s]; adduction, 20°; abduction, 6°; sursumduction, right, 2° +; left, 2° +; no hyperphoria; esophoria, 8°. Two days later, while wearing 2° esophoria prism, she disclosed 10° of esophoria with an abduction of 2°.

Treatment and Results.—The patient was at once given 4° of prism base out for her esophoria, and she wore them constantly for about six weeks with some slight improvement in her symptoms.

September 4, 1889.—A graduated tenotomy was performed on the right internal rectus. During the two weeks that followed this step, the choreic movements had almost entirely ceased.

October 8th.—A graduated tenotomy was performed on the left internal rectus. Two weeks later her father reported that she was going to school without bad effects, and was rapidly gaining flesh and strength. One month later he said that her dyspnœa had entirely disappeared.

November 11th.—Patient reports that prior to treatment she used to throw her pencils on the floor without knowing why, but has not done so since. She has no headache after study, as formerly, and has gained fifteen pounds in weight. The teachers in school have spoken to her parents of her marked improvement.

December 21st.—The right internal rectus was again divided, as some latent esophoria had been disclosed.

October 9, 1890.—Patient reports that she has had no chorea, and only an occasional headache.

Her muscular tests are: adduction, 20°; abduction, 7° +; sursumduction, right, 2° +; left, 2°=; right hyperphoria, ¼°; esophoria, 1°.

Reports from time to time during the past three years have been received from a neighbor, although the patient has not visited my office during this interval. From what I can learn, this patient continues to be absolutely free from any evidences of chorea.

The next case was one of the most surprising, both to myself and the patient, that I have ever encountered. The long persistence of the symptoms, the extreme physical weakness, the alarming attacks of laryngeal spasm that would occur without warning at intervals, and the tremor of the entire muscular system that persisted whenever any excitement or fatigue occurred, tended to make the prognosis grave and to justify a strong suspicion of organic disease.

(To be continued.)

[1] F. A. Davis: Lectures on Nervous Diseases. Philadelphia, 1888.

Actinomycosis.—The transmissibility of this disease to animals by direct inoculation has been studied by Professor M. Wolff and Dr. J. Israel, who have succeeded in making pure cultures from a case of actinomycosis hominis by sowing the granules on agar kept at 37° and devoid of air. The microbe is considered to be an anacrobe, yet a small quantity of oxygen does not prevent its growth. It grows very well in alkaline bouillon. The microscopical appearance of this microbe is said to be very variable—short and long rods, simple straight and branching or wavy filaments, cocci, and felt like masses are seen. The cocci are found free, but more frequently within the rods or filaments. The authors refrain from expressing a definite opinion as to their exact nature, but do not regard them as spores. They stain well by Gram's method. In none of the cultivations were club shaped elements met, but by injecting these cultivations into animals, tumors containing club shaped bodies were produced. Twenty-two animals were inoculated with the agar cultivations, and in all except one (a sheep) actinomycotic tumors were developed.

FORMS OF INTESTINAL OBSTRUCTION IN EARLY LIFE, WITH THEIR DIAGNOSIS.[1]

By JOHN DORNING, M.D.,

NEW YORK.

The time allotted to the part assigned me, of the subject to be discussed this evening, precludes anything more than a brief summary.

Clinically, intestinal obstruction is divided into an acute and a chronic form. Acute intestinal obstruction is characterized by a sudden onset, great urgency of the symptoms, and, unless speedy relief be obtained, usually a rapidly fatal termination. Treves mentions an ultra-acute form in which death follows a few hours after the initial symptoms. The chronic form is slower in its development, the symptoms are less severe, and the danger of death not so imminent. There are cases difficult to classify, but which might be termed subacute, which present symptoms of both acute and chronic obstruction. The varieties, or, perhaps, more correctly speaking, the causes of intestinal obstruction are:

1. **Congenital Malformations**; as, *a*, complete occlusion of the anus by a diaphragm of skin or membrane; *b*, absence of the anus, the rectum ending in a blind pouch at a variable distance from the perineum; *c*, the anus is present, but ends in a cul-de-sac, of varying length, the rectum also terminating in a blind pouch at some point higher up; *d*, absence of the rectum or some portion of the intestine; *e*, atresia of some part of the intestinal canal, the result of pathological changes during intra-uterine life.

2. **Intussusception or Invagination**, by which is meant the slipping of one portion of the intestine into an adjoining portion.

This is the most common form of obstruction observed in children. According to published statistics over fifty per cent. of the cases occur under ten years of age, and twenty-five per cent. and over during the first year. It is met with more often in males than in females.

Its varieties are ileal, ileo cæcal, ileo colic, colic, and colico rectal, according to the respective part involved.

3 **Volvulus, or the Twisting of the Bowel upon its Mesenteric Axis.**—This variety of obstruction occurs more frequently in adults than in children. In early life its most frequent site is at the sigmoid flexure.

4. **Constipation and Fecal Impaction.**

5. **Impaction of Foreign Bodies.**—The variety of foreign bodies swallowed by children, either accidentally or intentionally, is legion. One of my little two-year-old patients had a predilection for cloth as an article of diet. On one occasion, after she had suffered four days from obstinate constipation and vomiting, I removed from her rectum three pieces of woollen fabric that, when put together, measured forty-six inches in length by an inch and a half in width.

Foreign bodies give rise to obstruction, either as a mechanical impediment, because of their shape and size, or by the inflammatory swelling they set up by their presence. Round worms, by becoming rolled into a tangled mass, may cause intestinal obstruction. Insoluble mineral substances, as magnesia or bismuth, administered for a protracted period, may accumulate to such an extent as to form an obstruction.

6. **Constriction and Strangulation of the Bowel** by loops of intestine, fœtal bands (which are usually the result of peritonitis during intra uterine life), diverticula (as Meckels' diverticulum), by the forcing of a knuckle of intestine into a natural or unnatural opening, including hernia, both internal and external. Compression by an abdominal tumor, as an enlarged and displaced kidney.

7. **Stricture of the Intestine**, the sequel of a local enteritis, the most likely situation being in the cæcum at the ileo cæcal valve.

Ordinarily, the diagnosis of intestinal obstruction is not an exceedingly difficult matter, but in differentiating the particular form of obstruction the skill of the diagnostician is often taxed to its uttermost, and even then not always with success.

A child in apparently good health is seized with acute colicky pains, which soon become continuous. A convulsion may mark the beginning of the attack. Distressing and constant vomiting soon follows; at first the contents of the stomach are ejected, then the bile, and finally fecal matter. At first there may be several small evacuations from the bowels, accompanied by some degree of tenesmus, but absolute constipation shortly ensues. During the early part of the attack the abdomen may not be tender to the touch nor distended; later on there is a varying degree of tympanites, with pain on pressure. From the commencement of the attack the constitutional symptoms are generally quite pronounced. The face is pale and has an anxious expression. The temperature may be somewhat elevated, normal, or even abnormal. As the case progresses the pulse becomes very rapid and feeble. An insatiable thirst perhaps tortures the patient, the urine becomes scanty and high-colored and may even be suppressed. The features become pinched, the eyes sunken, and the skin covered with a cold and clammy perspiration. There is no longer complaint of pain. Unless relieved, at the end of from three to eight days the child dies in collapse.

The main symptoms upon which a diagnosis of intestinal obstruction is to be based are severe abdominal pain, persistent vomiting, and obstinate constipation. In determining the nature and location of the obstruction the age of the patient and the history of the case should receive due consideration, and a careful and thorough physical examination made under an anæsthetic if necessary.

In the new-born child constipation and vomiting would suggest the existence of congenital occlusion. If the vomited matter consist of a whitish mucus, the seat of the obstruction is likely to be high up in the small intestine. The ejection of meconium would point to an occlusion somewhere below the jejunum. By examination of the anus and rectum the existence of malformation in that locality can be readily discovered. If the obstruction be high up, palpation and percussion of the abdomen, in conjunction with the injection of water per rectum, may reveal the location, but not the nature of the trouble.

Intussusception being the most common form of intestinal obstruction encountered in children, it very properly should be the first thing to be either diagnosticated or excluded in every case presenting symptoms of acute obstruction. Severe paroxysmal pain is the earliest symptom. It, however, soon becomes continuous. The abdomen at first is not distended nor tender on pressure. Gentle rubbing of the abdomen usually affords some relief. Vomiting may set in, but it is not by any means a constant factor, and, even when present, may not become stercoraceous. Blood may be vomited if the intussusception involve the small intestine. Tenesmus sets in early, and is accompanied by a number of stools consisting of the fæces from that part of the bowel below the invagination, mucus, and blood. The nearer the invagination is to the rectum, the more marked the tenesmus. After this, constipation becomes insuperable. The temperature at first is normal, becomes elevated with the increase of the suffering, and sinks to below normal as the symptoms of depressed vitality supervene. Palpation of the abdomen will generally reveal a doughy, inelastic, sausage-shaped tumor, varying from two to six inches in length, in the region of the colon. This tumor will shift its location as more and more of the bowel becomes invaginated. Sometimes the lower end of the invaginated bowel can be felt with the finger high up in the rectum, and cases are reported where it has appeared outside the anus. If strangulation of the invaginated bowel does not take place, the symptoms are much less urgent, and the case may run a chronic course, and, perhaps, ultimately take on acute symptoms. In

[1] Read before the Section on Pediatrics of the New York Academy of Medicine, November 9, 1893.

rare cases the invaginated gut has sloughed off and been passed through the anus.

Volvulus and constriction and strangulation of a portion of intestine, as by a loop of intestine or an internal or external hernia, present similar groups of symptoms. There is the sudden attack of severe abdominal pain, constipation, vomiting, tympanites, and symptoms of profound constitutional depression. The constipation is absolute, neither fæces nor flatus passing through; sometimes there may be one action from the bowels from that portion situated below the seat of strangulation. It will not, however, contain either blood or mucus. In volvulus unequal distention of the abdomen, great tympanites on one side and flattening on the other, as mentioned by Erichsen, when present, may be of some assistance in making a diagnosis. Volvulus is most frequently located in the sigmoid flexure; hence it has been said that a rectal tube or soft sponge passed into the lower bowel will enable the diagnostician to detect an obstruction in that situation. As it is often difficult and sometimes impossible to pass a rectal tube throughout the sigmoid flexure under ordinary circumstances, not much reliance can be placed on this procedure as an aid in diagnosis. Injection of water through a rectal tube may give valuable information.

To make an absolute diagnosis of any particular form of constriction and strangulation of the bowel, unless by abdominal section, is often an impossibility. The possible existence of a strangulated inguinal or femoral hernia should always be thought of, and a careful examination made for such conditions. In this connection I would cite the case of a four-year old boy who had been suffering for thirty hours with abdominal pain, vomiting (which had latterly become stercoraceous), and constipation, and who had been given a number of copious enemata for the purpose of relieving some kind of an internal obstruction.

On examination I discovered a small strangulated inguinal hernia. Under chloroform it was reduced without difficulty, after which all the symptoms of obstruction disappeared.

In fecal accumulation the symptoms, as a rule, develop gradually. There is more or less abdominal discomfort for some days before the severe pain and vomiting come on. Then the history of the previous constipation, and the presence of a doughy tumor, which pits on pressure, in the region of the sigmoid flexure and the detection of fæces in the rectum will be sufficient evidence upon which to found a diagnosis.

Symptoms of intestinal obstruction, in connection with a history of the child having swallowed some object which, because of its shape, might have become lodged in the intestinal canal, and which it is positively known has not been passed per rectum, would make it appear probable that there was impaction of a foreign body. Should it happen to lodge in the rectum, tenesmus will be a marked feature in the case, and will of itself suggest a rectal examination. Under chloroform the foreign body might, in some cases, be felt through the abdominal walls. Nearer than this it is impossible to diagnosticate such a case.

Obstruction by intestinal worms is rather a hazardous diagnosis, even though the child may previously have been passing worms. In cases of this nature the diagnosis is usually made at the autopsy.

In obstruction due to stricture of the intestine the symptoms develop slowly, as in fecal impaction. A history of habitual constipation with stools of small calibre following a prolonged diarrhœa would be presumptive evidence of a stricture situated in the lower part of the intestine. The bowel below the seat of the stricture will be empty, while immediately above this point may be felt an elongated, boggy tumor representing the fecal mass.

Cases are occasionally encountered which present the characteristic symptoms of some form of intestinal obstruction, but in which no obstruction exists. Osler mentions a case of acute enteritis in which the symptoms were those of acute obstruction, but at the autopsy, the intestine was free from the duodenum to the rectum.

Sometimes appendicitis is mistaken for intestinal obstruction. The points of difference are said to be the elevation of the temperature, the absence of stercoraceous vomiting and tenderness at the McBurney point; but these symptoms can be misleading.

Not long ago there came under my observation the case of a young girl who, while in apparently fair health, was suddenly taken with pain in the upper abdominal region, persistent vomiting, which on the third day became dark-colored and had a decidedly fecal odor, and obstinate constipation. A diagnosis of intestinal obstruction had been made. I saw her on the evening of the third day. The vomiting of a dark, foul smelling substance continued; an unquenchable thirst harassed the patient; the pulse was rapid and feeble, the skin moist and moderately warm, the face anxious, and no complaint of abdominal pain; still, the abdomen was distended and tympanitic. She had voided no urine for twenty-four hours. Half an ounce of dark-colored urine drawn from the bladder showed on examination eighty per cent., by bulk, of albumin and epithelial blood, and granular casts. At the autopsy next day the intestines were found to be unobstructed; but the kidneys were the seat of chronic inflammation.

SOME OBSERVATIONS ON WATER-GAS.

By EDWIN A. DOWN, M.D.,

HARTFORD, CONN.

With the introduction of electricity as an illuminant, and the extraordinary precautions taken by hotel proprietors in placarding their rooms with the injunction, "Please turn off the gas; do not blow it out," much good has been accomplished in the way of preventing serious accidents due to the inhalation of illuminating gases. While this is a matter for congratulation, it is to be regretted that so little has been achieved in the line of scientific inquiry relating to phenomena produced by toxiferous materials which are among the furnishings of many of our households.

This seeming dereliction on the part of the profession may be accounted for partly for the reason that a physician's time is so occupied in visiting his many patients as to render it next to impossible for him to turn his attention to experiments requiring much time and labor, and which he considers should come within the province of the chemist, but chiefly from the fact that many members of the medical profession do not take into account the important distinction existing between the two illuminants, coal-gas and water gas.

In some instances it has been supposed that coal-gas, and not water-gas, was the agency causing death, and the natural inference has been that when medical assistance arrived asphyxiation had become so profound as to render resuscitation impossible.

With this conviction the matter has been allowed to rest; and as the physician in all probability does not have his attention drawn to the subject more than once a year in his own practice, its consideration is soon overshadowed by demands inseparable from the treatment of general diseases. To a closer observer, however, the subject becomes more interesting the wider the range of observation.

I have elsewhere [1] drawn attention to the fatal results following the inhalation of water-gas in considerable quantities, and I purpose in this place to discuss some of the effects produced by the exhibition of amounts not sufficient to jeopardize the life of the patient, but which are capable of producing most unpleasant symptoms, and in some cases so affecting the individual's health as to unfit him for his ordinary duties. A noteworthy instance of this occurred in the practice of Dr. J. J. Morrissey, of

[1] Proceedings of the Connecticut Medical Society, 1889.

Hartford, to whom I am indebted for the following history of the case:

Female; twenty years of age; occupation domestic; has complained of dizziness or "lightheadedness," which has been succeeded by intense frontal headaches coming on at frequent intervals. Medical treatment gave only temporary relief. Patient became weak and anæmic, when iron tonics in the most assimilable forms were administered, but no improvement was noticed. The patient was compelled to give up work, and went to reside with some of her friends. After removal to her new quarters the iron treatment was resumed, and was followed by most satisfactory results.

Upon further inquiry I ascertained that in her room in the house where she had been employed the gas-jet projected over the table where she had been accustomed to sit. Examination of the jet disclosed the existence of a small leak, which, while it did not admit of the passage of enough gas to be ignited, was sufficiently large to allow enough of the poisonous material to escape and vitiate the atmosphere of the room. During respiration this material was absorbed by the blood, and, combining with its elements, wrought such changes in its composition as to destroy, or at least inhibit, the functions of these elements: in this case operating to such an extent as to produce painful headache, besides rendering the absorption of the important substance, iron, an impossibility.

The *modus operandi* necessary to bring about such conditions will be considered in its appropriate place.

The statement that the symptoms in the case just related were due to exposure to water-gas is substantiated by evidence of an important character as follows: After leaving her position and before the leak in the gas-pipe was discovered, Miss M——'s successor, who occupied the same apartments as her predecessor, was compelled to resign her position owing to the presence of the same train of symptoms as enumerated in the history of the case just cited. Improvement and restoration followed her removal to other quarters. What is more convincing is the fact that since the discovery and stoppage of the leak in the pipe the occupants of this room have had no unpleasant experiences from this source.

Besides the symptoms enumerated, the head is also the seat of other unpleasant sensations, which, though often accompanied with headache, are as often present without it. Having experienced these sensations myself, I am in a position to describe them accurately.

First, there is a sensation of fulness in the head similar to that common to congestive headache without its accompanying pain. Then there is an exaggerated pulsation in the temporal arteries which is extremely annoying, and often attains such intensity as to resemble a slight blow from one of the fingers. The cutaneous nerves are frequently affected, and a subjective sensation of heat in the face, with or without paræsthesia in the arms, is a frequent accompaniment of this condition. Irritation of the bronchial mucous membrane is present in some cases, and was an important feature in several coming under my observation. Giddiness is a very common symptom, and is often observed when a person attempts to rise after being seated near a leaking gas-jet for a brief period. It is an interesting fact that persons suffering from cardiac disease are more susceptible to the influence of the poison than persons not so afflicted.

One of the remarkable properties possessed by carbonic oxide, the chief constituent of water-gas, is its power of resisting putrefaction in the bodies of those who have died from the effects of its inhalation. The longer the individual has been exposed to its action, the greater will be the interval between the death of the body and its commencing decomposition. This is accounted for from the fact that the carbonic oxide has formed such stable compounds with the various tissues as to retard their oxidation.

During the past year (1893) several fatalities due to the effects of water-gas poisoning have occurred in the city of Hartford. Actuated by a desire to continue my inquiries into a matter of so much importance to the public, I succeeded in obtaining, through the courtesy of the attending physician, a specimen of blood from one of the cases in which blood-letting was decided upon after consultation. Putting most of the specimen in a closely stoppered bottle, I took it immediately to State Chemist Dr. Herbert E. Smith, of New Haven, who after a careful analysis of the sample found it to contain between two and three per cent., by volume, of carbonic oxide.

Inasmuch as it has been a disputed question concerning the amount of carbonic oxide taken into the circulation, the result of Professor Smith's investigation becomes extremely valuable. Examined under the microscope the blood in water-gas poisoning presents no features that are characteristic. The corpuscles appear to be shrunken and irregular in outline, while some seem to be nucleated. It is probable that this shrinking, in connection with the chemical changes wrought in the hæmoglobin, is an important factor in producing the cherry-red color noticed in the blood of persons asphyxiated by carbonic oxide. It requires an exposure of several hours before these changes can be observed; for passing a column of gas through defibrinated blood for ten or fifteen minutes produces no marked change in the form of the corpuscles.

In addition to the above morphological characters, the blood, owing to the changes affecting its hæmoglobin, is rendered incapable of absorbing one of its important constituents, iron. This is a very important point, and should not be passed over with indifference. For, if a study of the case mentioned in the beginning of this paper teaches anything, it is that the inhalation of carbonic oxide, whether in a free state or in combination as water-gas, is capable of inhibiting the absorption of so important an element as iron, and for this reason becomes of much importance therapeutically. In health iron is present in amount equal to nearly three grammes in a person of average weight. It is derived from ordinary foods as they are digested in the system, and is essential to the respiratory functions of the hæmoglobin. Hence the importance of eliminating all influences which tend to prevent its absorption.

This whole subject opens out a field of inquiry which is very inviting from the important character of the results which are promised.

If we now turn our attention to a consideration of the manner in which the effects detailed are brought about, we will find that the operation is not a simple one; but, on the contrary, if we include the nerve elements involved, the process will be found to be not only indirect, but even elaborately circuitous.

Beginning with the admixture of the gas with the atmosphere its introduction into the lungs speedily follows. Thence it passes through the walls of the vesicles and capillaries into the blood. Arriving at this point, it appears to have a selective action on the hæmoglobin of the corpuscles, with which it rapidly combines. Swept along with the blood-current it soon reaches the nerve-centres controlling the vital functions, and, as I believe, exerts a direct toxic effect on the nervous elements, as well as acting in a negative manner, by depriving these elements of their vitalizing agency, oxygen.

In support of the former proposition the experiments of Traube and others afford a suitable confirmation. These experiments were so conducted as to allow the injection of blood saturated with carbonic oxide into the circulation of animals without abstracting any portion of the oxygenated blood; and, although the amount injected was small, dyspnœa was produced in every case. These tests seem to prove that, although oxygen may exist in the blood in normal amounts, the nerve-centres are susceptible to the toxic action of carbonic oxide in comparatively small quantities.

Blood containing carbonic oxide after being defibrinated and properly diluted exhibits a characteristic absorption spectrum. This consists of two absorption bands similar to those of oxyhæmoglobin, but located

nearer the violet end of the spectrum; and what is very noticeable, these bands do not disappear after the addition of reducing agents, as is the case with oxyhæmoglobin. The compound crystallizes like oxyhæmoglobin. An excess of a soda salt brightens blood containing carbonic oxide, while it darkens normal blood.

The immediate cause of death in poisoning by carbonic oxide I believe to be due to an exhaustion of the nerve-centres, induced by the prolonged action of the gas which is present in the blood, and which is not eliminated in time to admit of resuscitation. In cases of poisoning by water-gas the patient, formerly in robust health it may be, lingers for two or three days—which happened in one of the cases in this city last year—and then dies suddenly from exhaustion, the nerve centres being worn out If it were possible to maintain the heart's action until the formation of new corpuscles sufficient to convey even a small amount of oxygen to the tissues, the results would be more encouraging. Unfortunately, the heart succumbs before the desired condition can be accomplished. Cardiac stimulants, artificial respiration, and the application of electricity to the phrenic nerve are always thought of and used most faithfully, the only effect being a moral one upon the bystanders.

The foregoing refers to cases which have been exposed to the gas for six or eight hours, and are thoroughly asphyxiated, using the term in its technical signification. When only partial asphyxiation occurs, enough oxygenated blood is left to carry on the vital functions, though with some discomfort.

Regarding the changes in the blood which occur when a person recovers after slight exposure, my own theory, which awaits confirmation, is that by a process of katabolism the affected corpuscles are gradually removed, and others, fresh from the "blood islands," are substituted. It is to be regretted that water-gas, while possessing such high illuminating properties, should carry concealed within itself such an element of destruction as the much-dreaded carbon-monoxide.

Recognizing this fact the legislature of Massachusetts passed an act authorizing the gas commissioner to license certain gas companies to make and sell water gas for illuminating purposes. Section 2 of said act (chap. 428, Acts of 1888) says: "Any company who shall under the provision of the first section of this act be licensed to make and sell water-gas for illuminating purposes containing an excess of ten per cent. of carbonic oxide shall furnish to every actual consumer a copy of the gas commissioner's license, which shall contain a statement of the percentage of carbonic oxide such gas contains, as near as the same can be ascertained."

Only four cities in Connecticut have established plants for the manufacture of water-gas: Hartford, Middletown, Waterbury, and Willimantic. While these do not represent a majority of the population of the State, their citizens are entitled to protection from this harmful element by the passage of an act similar to the one by which the citizens of Massachusetts are protected.

Having discharged my duty as a physician in directing the attention of the State and local boards of health to a matter of hygienic importance affecting many of the citizens of our State, it only remains for me to add that a knowledge of the *personnel* of the various boards of health is sufficient guarantee that the subject will be given the consideration its importance merits.

Convalescent Children.—A new occupation for women is suggested, says a writer in *The Times*, in the proposed establishment of an association for the care of convalescent children. Members are to be sent out like nurses for short periods. A child has scarlet fever, perhaps; he is separated from his brothers and sisters, and most likely has a trained nurse, who, though invaluable in actual illness, is not equal to the tedious recovery period. It is here that the cheerful, educated, child-loving woman is to step in and take the burden off the mother.

Progress of Medical Science.

Infant Feeding.—In the *American Medico-Surgical Bulletin*, some practical points in infant feeding are made by Louis Fischer, M.D., of this city. The most important of these is the reiteration of the well known fact that every mother should be her own child's wet-nurse whenever possible. In cases where the mother is much exhausted, is suffering from tuberculosis, or some marked nervous state, the maternal organism should not be called upon to supply the infant's food. Syphilitic babies, those who inherit syphilis, should only be nursed by their own mother, since the risk of infecting a wet-nurse is so great. The life of the syphilitic child often depends upon its receiving milk from its own mother. Whenever children remain below normal weight, though apparently in perfect health, they must be weaned. If a woman discovers that she is pregnant, the nursling should be weaned immediately; though this need not be done simply because menstruation has returned. The weaning process should be gradual, from the eighth to the tenth month. Unless for some special reason, infants should not be fed at night. Prolonged and useless nursing induces rachitis. After the tenth month, little children need other food than their mother's milk.

When the mother cannot nurse her own child, a wet-nurse should be immediately secured. She must be carefully examined as to her physical condition. Tuberculosis, chronic disease, hereditary nervous troubles, epilepsy, and syphilis exclude nursing. The milk must also be examined microscopically. The proof of the value of a wet-nurse is to be found in the nursling. If the baby thrives, it will increase in weight. Hence the necessity of weighing it frequently. Never give any food preparation containing starch during the first three months. As cow's milk differs so much from human milk, it must be diluted by adding substances which increase its digestibility and prevent its curdling. Oatmeal gruel may be added when constipation exists, and barley when there is a tendency to diarrhœa. In making these gruels the entire grains (shells) should be used, as these contain a certain amount of albuminoid. Sugar is added by using sugar of milk, and the salt supply is the ordinary table salt. The milk should come from several cows, to avoid the exclusive use of a secretion from any one animal that may possibly be diseased. The milk used should always be sterilized.

Dropsy of Bacterial Origin.—Dr. H. J. Hamburger found in ascitic fluid taken from a dropsical patient a micro-organism, hitherto unknown, which he calls bacterium lymphagogon. To the pathogenic action of this organism on the capillary endothelium he ascribes the excessive increase of lymph which produces the ascites. This power is destroyed in the organisms by exposing them for two hours to a temperature of 56° F. In form the microbes resemble micrococci; they are only moderately motile; the average size is from 0.5 to 0.8 μ. They are easily colored by the usual methods, and require a large amount of oxygen. Cultures in beef, veal, and horseflesh broth were unsuccessful. The growth of the organisms is exceedingly rapid in liquid human serum and in sterilized ascitic fluid. Hamburger points out the fallacy of relying on the liquefaction of gelatine as a distinctive feature of special kinds of bacteria. In his cultures he found this to vary in accordance with the use of fresh-made gelatine or of such as had been in stock for some time. He opposes the view of Cohnheim (*Vorlesungen über allgemeine Pathologie*, 2 Aufl., Th. I., p. 494), who maintains that every form of dropsy is caused either by excessive venous hyperæmia, or by the increased permeability of the walls of the capillaries. Hamburger points to a third form—stimulation of the capillary endothelium by a substance produced by bacteria.—*The British Medical Journal.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, May 5, 1894.

ANOTHER STATE MEDICAL INSTITUTION.

THE last Legislature at Albany passed the bill establishing an epileptic colony at Sonoma, N. Y. The new institution is to be called the Craig Colony, and doubtless it will soon be in practical operation.

There are a large number of epileptics in the State who can undoubtedly be cared for best on the colony system. It is a wise and humane method, and one which has stood the test of practical experience in European countries.

We have before expressed the opinion, however, that the assumption by the State of the care of its paupers and indigent epileptics was a measure of doubtful expediency. It is another step toward institutional medicine or medical socialism. We were, we confess, among those who, a year ago, rejoiced over the new plan of putting all the insane under the care of the State; but already "politics" has crept in, reforms are called for, and the happy auguries for the better care of the insane have not come true. We shall expect before long to see the Craig Colony one of the spoils of party conflicts. If the State takes care of its indigent epileptics, the next proposal will be to establish State hospitals for the consumptive. Already propositions for such schemes are in the air; enthusiastic humanitarians and sanitarians can formulate most convincing reasons for the public care and isolation of this class.

This tendency to institutionalism in medicine is unfortunate, and if not checked will prove disastrous. It means a medical bureaucracy, with a corresponding paralysis of individual effort and ambition. Against such a state of things it is the duty of physicians to use their influence in every possible way. In the dim future when everyone has become wise, industrious, unselfish, yet hopeful and ambitious, we can trust medical affairs perhaps to States and syndicates, but the world is not yet good enough. We have worked many years to secure a reasonably intelligent care of the insane by the State, and there are still many things lacking. We trust that the epileptic colony will get a good "boss," such a boss it is bound to have, and that it will be several years before it becomes the object of visits by investigating committees. If by chance it strikes at once upon a high scientific plane, we trust it will not be Elmiraized like Mr. Brockway's Reformatory, in order to promote the circulation of sensational newspapers.

WOMAN'S SUFFRAGE AND WOMAN'S BRAIN.

THE present very active and enlightening agitation over the question of woman's suffrage, calls up again the many now established facts about the physiological differences in the nervous system of the sexes. Not very long ago, Sir James Crichton Brown delivered a series of lectures in which he aimed to show, from actual data, that the brains of women were not only relatively smaller but essentially different in structural arrangement and functional characteristics from those of man. He in particular showed that the vertebral arteries in women are larger in proportion to the carotids than they are in men, and that the cerebellum and posterior parts of the brain were therefore more nourished proportionately. The brain of woman is four per cent. smaller than that of man after deducting the factors of height and weight (Debierre), and woman's brain, as soon as it reaches its apogee immediately begins to decline in weight, so that senile atrophy is manifested sooner than in man.

There is no doubt, we believe, in the minds of physiologists that the mental characteristics of woman have a structural basis in the conformation and amount of her nervous tissues, and that no amount of training will make the male and female brain alike.

Of course, all this does not in the least prove that woman's mind is not adapted to the demands of suffrage, or of political, jury, and militia duty. It only shows that the result of conferring suffrage cannot be positively predicted either one way or the other, since it would be injecting into our political system an entirely new factor.

We admire the eloquence and are affected by the enthusiasm of the agitators for and against suffrage. But we have little faith in those who assure us that it would surely be a blessing—or a curse—if women went to the polls and sat in the jury-box. It is an experiment which may or may not turn out wisely.

THE SARSAPARILLA HUMBUG.

THE esteemed editor of the *Therapeutic Gazette* comes to the rescue of sarsaparilla, and says that it ought to be retained in the Pharmacopœia because it covers the taste of iodide of potassium. This would be rather a weak excuse, even if it were true. But it does not happen to be true, as anyone can be convinced by a trial.

The *Gazette* further puts forth the weird hypothesis that sarsaparilla syrup promotes the action of iodide. We venture to say that there is not a scintilla of clinical proof that this is the case. The most brilliant results from iodide have often been obtained by enormous doses, after small doses combined with sarsaparilla have failed.

The fact is that the legendary belief in sarsaparilla as a "blood purifier" promotes no end of quackery and useless drugging. Hence physicians, at least, ought to rid themselves of false notions about it.

Baron Hirsch's Gifts to Medical Charities.—Baron Hirsch, who last year distributed among selected charities a sum of about £42,000, has this year provided a sum of £15,000 to be divided among London hospitals and charitable institutions. The London Hospital is the recipient of £1,000, and the Brompton Hospital for Consumptives receives £600, while St. George's Hospital and Charing Cross Hospital each receives £500.

A NEW HOSPITAL FOR CONSUMPTIVES.

A MEETING of ladies and gentlemen was held last week in this city to perfect the organization of a hospital and dispensary for the treatment of consumptives. The movement has the support of Drs. A. L. Loomis, Charles McBurney, Henry F. Walker, William M. Polk, A. A. Smith, Charles E. Quimby, and others.

A long article in *The Evening Post* of the same date gives an account of the purpose of the meeting. There is, it is said, need of more accommodation for patients suffering from consumption. There are in this city 81 hospitals, with a total number of 10,807 beds, of which 8,500 are free. But of these only 710 are devoted to consumptives, and less than 600 are available for free patients. The list of hospitals for incurables is given as follows: St. Joseph's, 300; Home for Incurables, 180; Montefiore Home, 150; Isabella Heimath, 60; House of the Holy Comforter, 20.

These institutions are mostly of Catholic or Hebrew provision, and the non-Catholic and non-Jewish part of our population is relatively very inadequately provided for.'

The view is urged, therefore, that another hospital for incurables, or more especially for consumptives, be established, and one that will be non-sectarian in character.

INFECTION AND THE COMMUNION CUP.

THE suggestion that there is danger of communicating disease by the use of a common cup in the administration of the communion has been often made in the past few years. The idea of there being physical danger in the sacrament is naturally one not quickly received, and until quite recently has not been seriously discussed. The establishment of tuberculosis among contagious diseases, however, has given a fresh impetus to public feeling regarding the need of hygienic measures; and decisive action in the matter of the administration of the communion has at last been taken by one of the churches at Rochester, N. Y. At a ministers' meeting in that city, on March 5th, Dr. W. S. Ely made a statement of the dangers attending the present method, and the unanimous sentiment of the thirty-five ministers present was, that in view of the statements made, there must be a change.

A committee was appointed and it made a report recommending the use of small individual tumblers, about sixty of which could be placed on a tray of convenient size. This plan will be adopted at the next communion, in June.

Since clergymen find that the sacrament can be administered with equal ease and propriety by individual cups, there is good reason that this method should be adopted. We are not sanitary alarmists, and it must be conceded that the dangers of the ordinary way are slight. But since they do exist, it is wisest to remove them.

Medical Association of the State of Alabama.—The annual meeting of this Society was held in Mobile, on April 16 and 19, 1894. The President of the Association is Dr. Richard Matthew Fletcher, of Madison, and the Secretary, Dr. James Reid Jordan, of Montgomery.

News of the Week.

The Death of Dr. A. C. Stanard.—*Whereas*, Dr. Albert Cushman Stanard, an esteemed member of the Harvard Medical Society of New York, has in the infinite wisdom of God been called thus early to lay aside the duties of life, cut down in the vigor of early manhood, as the paths of usefulness and promises of prosperity were opening wide to him; therefore be it

Resolved, That in his untimely death we recognize the loss to the Society of one of its most promising and worthy members, and desire to pay to his memory a tribute of sincere respect;

Resolved, That we extend to his stricken sisters our heartfelt sympathy at the grief which has come upon them;

Resolved, That these resolutions be published in the MEDICAL RECORD. (Signed)

JOHN B. WALKER, M.D.
WILLIAM B. COLEY, M.D.
JOHN H. HUDDLESTON, M.D.

The Ohio State Medical Society will meet in Zanesville, May 16th, 17th, and 18th.

The Academy of Medicine of Cincinnati has adopted resolutions in which it says that, *Whereas* it considers the Library of the Surgeon-General's office in Washington of the greatest importance to medical education and to the medical profession throughout the entire country; and they believe that it is for the public good that it should receive the liberal support of the Government;

Resolved, That the Academy of Medicine desire to enter their earnest protest against the reduction of the appropriation for its annual support from $10,000 to $7,000;

Resolved, That the Academy of Medicine urge most strongly the restoration of the former annual appropriation of $10,000, under which it has become one of the largest and best appointed medical libraries in the world, and without which its continued growth would be seriously crippled.

The National Association of Railway Surgeons will meet in Galveston, Tex., May 8th, 9th, and 10th.

The New Riverside Hospital at Yonkers has received an endowment of $40,000 from Mrs. John B. Trevor.

Dr. William E. Cuff has been appointed deputy coroner to Coroner Shea, to serve out the term of Dr. Conway, deceased. Dr. Cuff was educated at St. Francis Xavier's College, and the University Medical College.

Catholicism and Coroners.—A correspondent writes to ask us why our city's deputy coroners are always Catholics. We do not know if it be so, but trust that the next constitutional convention will provide means for doing away with the whole wretched system.

Dr. Reuben A. Vance, of Cleveland, died on March 19th, aged forty-nine. Dr. Vance was born in Gallipolis, O. He graduated in medicine at Bellevue Medical College, and practised in this city until 1876, when owing to ill health he went to Ohio, and commenced practice in his native town, Gallipolis, O. Three years later he removed to Cincinnati, and for two years was

lecturer on pathological anatomy in the Cincinnati College of Medicine and Surgery in that city. In 1881 he came to Cleveland to accept the chair of surgery and clinical surgery in the medical department of the University of Wooster. Later he resigned, but has since practised in Cleveland. He was a recognized surgical authority, and was a large contributor to medical literature.

The Cincinnati College of Medicine and Surgery has become affiliated with the Cincinnati University as one of the institutions sustaining that relation.

The Prevention of Tuberculosis.—The following circular of information to physicians regarding the measures to be adopted for the prevention of tuberculosis in the city of New York has been issued by the Health Department.

"The communicability of pulmonary tuberculosis has been so thoroughly established, and is now so generally recognized by the medical profession throughout the world, that the Board of Health of New York City has determined that the time has arrived when active steps should be taken, looking toward its prevention in this city. The Board has therefore resolved to adopt the following preliminary measures :

First.—The Department will hereafter register the name, address, sex, and age of every person suffering from tuberculosis in this city, so far as such information can be obtained, and respectfully requests that hereafter all physicians forward such information on the postal cards ordinarily employed for reporting cases of contagious disease. This information will be solely for the use of the Department, and in no case will visits be made to such persons by the inspectors of the Department, nor will the Department assume any sanitary surveillance of such patients, unless the person resides in a tenement-house, boarding-house, or hotel, or unless the attending physician requests that an inspection of the premises be made ; and in no case where the person resides in a tenement-house, boarding-house, or hotel will any action be taken if the physician requests that no visits be made by inspectors, and is willing himself to deliver circulars of information, or furnish such equivalent information as is required to prevent the communication of the disease to others.

Second.—Where the Department obtains knowledge of the existence of cases of pulmonary consumption residing in tenement-houses, boarding-houses, or hotels (unless the case has been reported by a physician and he requests that no visits be made) inspectors will visit the premises and family, will leave circulars of information, and instruct the person suffering from consumption and the family as to the measures which should be taken to guard against the spread of the disease, and, if it is considered necessary, will make such recommendations for the cleansing or renovation of the apartment as may be required to render it free from infectious matter.

"Third—In all cases where it comes to the knowledge of the Department that premises which have been occupied by a consumptive have been vacated by death or removal, an inspector will visit the premises and direct the removal of infected articles, such as carpets, rugs, bedding, etc., for disinfection, and will make such written recommendations to the Board as to the cleansing and renovation of the apartment as may be required. An order embodying these recommendations will then be issued to the owner of the premises, and compliance with this order will be enforced. No other persons than those there residing at the time will be allowed to occupy such apartments until the order of the Board has been complied with. Infected articles, such as carpets, rugs, etc., will be removed by the Department, disinfected, and returned, without charge, to the owner.

Fourth—For the prevention and treatment of pulmonary tuberculosis it becomes of vital importance that a positive diagnosis shall be made at the earliest possible moment, and that the value of bacteriological examinations of the sputa for this purpose may be at the service of physicians in all cases not under treatment in hospitals, the Department is prepared to make such bacteriological examinations for diagnosis, if samples of the sputa, freshly discharged, are furnished in clean, wide-necked, stoppered bottles, accompanied by the name, age, sex, and address of the patient, duration of the disease, and the name and address of the attending physician. Bottles for collecting such sputa, with blank forms to be filled in, can be obtained at any of the drug-stores now used as stations for the distribution and collection of serum tubes for diphtheria cultures. After the sputum has been obtained, if the bottle, with the accompanying slip filled out, is left at any one of these stations, it will be collected by the Department, examined microscopically, and a report of the examination forwarded to the attending physician free of charge.

"Fifth—The authorities of all public institutions, such as hospitals, dispensaries, asylums, prisons, homes, etc., will be required to furnish to the Department the name, sex, age, occupation, and last address of every consumptive coming under observation within seven days of such time.

"It is the earnest wish of the Board of Health that all practising physicians in this city co-operate with the Board in an earnest and determined effort to restrict the ravages of the most prevalent and formidable disease with which we have to deal.

"By order of the Board of Health,

"Charles G. Wilson, *President.*

"Emmons Clark, *Secretary.*"

The Medical Association of India.—A meeting of medical men in Calcutta was held on February 21st, to effect an organization of the Medical Association of India. The membership is not confined to practitioners resident in Calcutta, although the headquarters of the Society is in that city. The first president of the Association is Dr. Jagobundhu Bose ; vice-president, Dr. Soorjie Coomar Sarbadhicary ; treasurer, Dr. S. Bachoo ; and joint secretaries, Drs. A. L. Sandel and Lawrence Fernandez.

The Cat as a Cause of Insomnia.—An ingenious Brooklyn statistician estimates that United Brooklyn has over 100,000 cats, of which more than one-half are unsheltered. He considers it as a conservative estimate that ten per cent. of the 1,000,000 inhabitants of our sister city are kept awake at night by the howling of the 100,000. This makes one case of insomnia per cat, and leads one to the conclusion that Brooklyn is a very sleepless city. If cats and insomnia prevail with equal virulence in

other cities, it would follow that there are 6,000,000 cats and 6,000,000 cases of insomnia in America. Yet no notice is taken of this pathogenic factor by systematic writers on sleep.

Missouri Medical College.—The fifty-third annual commencement exercises of the Missouri Medical College, the oldest west of the Mississippi River, were held last month and diplomas awarded to forty-seven graduates.

The Doctor in Fiction.—The *Boston Medical and Surgical Journal*, in discussing this subject, finds but few creations which represent the medical man with vitality and truthfulness. First of all is placed Balzac's "Médecin de Campagne." George Eliot's Dr. Lydgate in "Middlemarch" is a realistic portrayal; and Dr. Sevier, in one of Cable's stories, ranks among the very best of novelists' creations. This is only three out of hundreds of attempts to portray the physician. We quite agree with our contemporary in its critical estimates.

A Tournament of Strong Men has been proposed by Dr. Sargent, of Harvard. St. Louis has been selected as the place in which it will be held.

Pruritus Vulvæ from Jealousy.—Once, says Dr. William Goodell, I was asked by a medical friend to see an exceedingly bad and acute case of pruritus vulvæ; the very worst that ever came under my observation. The lady was tossing about in her bed in a state bordering on frenzy from the intense itching, which could be allayed only by cold starch poultices applied every few minutes. Very naturally attributing it to uterine disease, my friend had discovered a small but angry-looking tear in the cervix, exuding a viscous discharge, and I was called in to the case to decide the question of an operation. I, too, was at first led astray; but the suddenness of the seizure, its vehemence, and the lack of consistency in the behavior of the symptoms, put me on my guard, and we soon found out the cause to be an attack of jealousy. This was a stubborn case to manage, but she ultimately recovered under isolation, massage, and heroic doses of asafetida.

Twice I treated a highly intellectual lady for attacks of pruritus vulvæ, and of vaginismus. The itching was intolerable, and the sensitiveness of the genitalia so acute as to forbid every attempt at sexual intercourse. Each attack was brought on by mental overstrain, from exacting literary work, and much domestic unhappiness ensued. Several cases, I have personally known, of ladies who had for months been treated for supposed uterine or ovarian disease, when their whole and only trouble was remorse at having had illicit intercourse, or at having resorted to criminal abortion.

Connecticut Vital Statistics and Medical Practice Act.—The annual report of the Connecticut Board of Health just issued for the year 1892, shows that only 42.2 per cent. of the children born in the State were of American parentage. In forty per cent. both parents were of foreign birth, and during the ten years from 1883 to 1892 the foreign birth percentage rose from 38.5 per cent. to forty per cent., while the native births sunk from 45.5 to 42.2 per cent. The illegitimate births recorded were 196 out of a total of 19,750. In the diseases causing death, consumption, with 1,386 deaths out of a total of 15,170, leads every disease but pneumonia, though its decrease is indicated, as the average for the ten years was 1,448. A considerable increase over the average of ten years is indicated in nearly all diseases of the heart. Influenza carried off 564, as compared with a yearly average of 114 for the ten years. Pneumonia carried off 1,493, as compared with an average for the ten years of 1,079. The last Legislature passed a medical practice act after a very hard contest. Its chief provision was for registration of physicians on or before October 1, 1893, non-graduate physicians registering after that date having to submit to an examination, and all physicians opening themselves to a severe penalty if practising after that day without registration. The report states that under this law a great number of resident quacks have registered, some of whom in their applications show the most gross illiteracy. An examination of the list of registered physicians shows that many of the leading practitioners in the State have not complied with the law. Altogether the new law seems to have proved of little value except as a basis for future legislation in this State. Since 1848 the death-rate of the State per 1,000 has risen from 12.4 per cent. to nineteen per cent., and the birth-rate from twenty per cent. to 24.7 per cent.

Cholera in Europe.—The disease is very prevalent in Galicia and Russia, and has made its appearance in France. Twenty-eight cases and eleven deaths have occurred in the former place. At Koons, in Russia, fifty-five cases and thirty-three deaths. Eighty-seven cases of cholera, or cholerine, were reported to the health authorities of Lisbon. The reports stated also that there had been 122 recoveries from the disease, and that 440 patients are still under treatment. One death from cholera was reported up to April 27th. A medical commission has been created by royal decree to act with the civil governor in the adoption of measures to check the spread of cholera. A quarantine has been declared at Antwerp against all vessels arriving from Portuguese ports.

Indiana State Medical Society.—The forty-fifth annual meeting of the Indiana State Medical Society will occur in Indianapolis, Thursday and Friday, May 17 and 18, 1894. The sessions will be held in Plymouth Church, southeast corner of Meridian and New York Streets. Arrangements have been made with the Central Traffic Association whereby the usual one-and-one-third railroad rate may be secured by those desiring to attend the meeting. Dr. Frederick C. Woodburn is the Chairman of the Committee on Arrangements.

Germ-proof Filters.—Taking the results of five different experiments to test the value of the unglazed porcelain filters known as the Pasteur-Chamberland system, I find that these investigators all accord in stating that the power of these filters for doing perfect work is of short duration. It is clear that such filters should not be used for a longer period than a week, under any conditions, without a thorough cleansing. The Chamberland filter is undoubtedly the best for use in the laboratory, but it has defects which may eventually be remedied. The experiments above referred to are from both French and German sources.

Nothing in it.—A dentist who recently committed suicide willed his brain to Cornell University.

Reviews and Notices.

Popular Essays on the Care of the Mouth and Teeth. By Victor C. Bell, A.B., D.D.S.

This little book has just appeared, comprising about one hundred pages. It is written to diffuse a more general knowledge of dentistry to the layman, and seeks to fill a long-felt want.

It is abundantly illustrated and gives numerous recipes for lotions and dental powders.

It is only necessary to refer to the chapter on micro-organisms, which has been copied from Professor Miller, of Berlin, to see that the author's desire to give an up-to-date work has been accomplished.

We welcome the first edition with all its merits and demerits, and believe that, although the article on antiseptic and antacid is not in accordance with modern scientific teaching, still we commend it to the profession.

Medical Society of New Jersey. Transactions for 1893.

A volume too large for the amount of useful information contained. The suggestion from Hunterdon is a good one, that the "Transactions" be improved "so that they would be more in harmony with modern methods and usages." The reports of district societies might be much condensed or omitted. The President's address on "Therapeutical Superstition" is worth reading.

The Dispensatory of the United States of America. By Dr. George B. Wood and Dr. Franklin Bache. Seventeenth edition. By H. C. Wood, M.D., LL.D., Professor of Materia Medica and Therapeutics, University of Pennsylvania, and Joseph P. Remmington, Ph.M., F.C.S., Professor of Theory and Practice of Pharmacy, Philadelphia College of Pharmacy; Samuel P. Sadtler, Ph.D., F.C.S., Professor of Chemistry, Philadelphia College of Pharmacy. Royal 8vo, pp. 1930. Philadelphia: J. B. Lippincott Co. 1894.

Following closely upon the publication of the United States Pharmacopœia, notice of which has already been given in a previous issue of the Medical Record, the United States Dispensatory appropriately follows as an addendum and commentary to the same. Its seventeenth edition, now at hand, proves that this remarkable and exhaustive work improves with age and is progressive in its wide spread usefulness. The present edition is necessarily enlarged to make room for the large number of new remedies which have appeared since the previous issue. Never, in a similar period, has so much activity been displayed in the discovery of new compounds and in their practical application to therapeutics. The list is very fully given, so that no one who consults the volume for reliable data under this head need be disappointed. In this respect it still maintains its reputation as a trustworthy reference book for both pharmacist and physician. The metric system is adopted, in accordance with the suggestions of the Pharmacopœia, but the editors, considering the need for education in regard to it, have wisely placed the old and new systems of weights and measures side by side for comparison. Although, scientifically speaking, the metric system is the proper one, the majority of pharmacists and physicians are not yet ready to put it to every day practical application. Following also the suggestion of the Pharmacopœia, the new chemical nomenclature has been adopted, requiring that the basylous or metallic component of the compounds shall be placed first. The atomic weights of Meyer and Seubert, or the molecular weights based upon them, are placed at the head of each chemical article in bold type, while on the right-hand side of the page are placed in ordinary Roman type the molecular weights most commonly used in calculations. This arrangement is a very satisfactory and practical one, as is also that of placing the index of diseases in the fore instead of the back part of the volume. Although much enlarged in consequence of the new matter added, and principally under new remedies, the pages are so increased in size as not to make the work unwieldy for the shelf or too bulky for every-day reference. As a whole, the work will fulfil all the acknowledged necessities of its publication, and will fully maintain its well-earned reputation for accuracy and usefulness.

Text book of Nervous Diseases. Being a Compendium for the Use of Students and Practitioners of Medicine. By Charles L. Dana, A.M., M.D.; Professor of Nervous and Mental Diseases in the New York Post-Graduate Medical School, and in Dartmouth Medical College; Visiting Physician to Bellevue Hospital. Second edition. With two hundred and ten illustrations. New York: William Wood & Co. 1893.

That Dr. Dana's text-book has been thoroughly appreciated by the profession is amply attested by the appearance of this new edition within so short a time of the first one. An examination of the present volume shows that recent advances in the department of neurology have been duly considered by the author in various corrections and additions to the body of the book. A supplementary chapter on neurological therapeutics will prove of special interest and value to the general practitioner, who may need advice bearing on the treatment of particular cases. Hydrotherapy and the popular rest treatment are set forth in some detail, and altogether this subject of treatment is more fully set forth than is the case in many other works on nervous diseases.

The author is now inclined to discard the older views on neuro-pathology, and to ascribe many degenerative neuroses to the toxæmic effects of micro-organisms. This is certainly an attractive view, and while not yet generally accepted by other authorities, will possibly lead to a reconstruction of our ideas on the essential nature of many puzzling disorders. On the whole, Dr. Dana's work is concise, reliable, and clear. Its teachings are modern and yet sufficiently conservative to make them eminently safe.

Medical Society of North Carolina. Transactions for 1893.

Contains a number of fair reports, including an illustrated "Plea for the Microscope," by Hays.

New Jersey Board of Health. Seventeenth Annual Report, including Report of Bureau of Vital Statistics.

A volume of over six hundred pages and correspondingly heavy. Much information in sanitary matters can be found by one interested in its search.

American Association of Obstetricians and Gynecologists. Transactions for 1893.

The members have thought their various contributions worthy of excellent paper, ink, and binding, and for the most part they were right. The illustrations add to the reasons for keeping the report among one's books. An excellent portrait with memorial sketch of George Jackson Fisher, M.D., completes a very creditable production.

The Physiology of Death from Traumatic Fever. A Study in Abdominal Surgery. By John D. Malcolm, M.B., C.M., Fellow of the Royal College of Surgeons of Edinburgh, etc. London: J. & A. Churchill.

In an interesting way are discussed the conditions of the vessels during inflammatory fever; effects on cardiac rhythm; causes of pulse conditions in fever; the effects of the vascular changes brought about by traumatic fever; effects of a wound on the vascular and thermal systems; and the mode of action of the poisons of specific and septic fevers. It is a little volume of 130 large print pages, and will especially interest those engaged in abdominal operations.

Atlas of Clinical Medicine. By Byrom Bramwell, M.D., F.R.C.P. Edin., etc. Vol. I., part IV.; vol. II., parts I. and II. Pp. 142 to 182; 1 to 44; 45 to 90. Edinburgh: T. & A. Constable. 1893.

The later fasciculi of this interesting and most valuable work contain large plates and woodcuts of the same high order of merit that characterized the earlier instalments. The fourth part of volume first has four plates illustrating small-pox; three, melancholia; and one illustrating hilarious mania. The subjects considered are small-pox, globulinuria, Friedreich's ataxia, a case of chronic insanity and a case of hilarious mania. In part first of volume second the subjects are scrofula, unilateral hypertrophy of the skull, measles, two cases of Friedreich's ataxia in which the knee-jerks are not lost; alterations in the fields of vision, their clinical significance and importance. The following are the plates: two illustrating scrofula; two hypertrophy of the skull; one, measles; perimeter charts showing alterations in the fields both for white and for colors in cases of hemianopsia; naked eye appearance of the brain in two cases of lesion of the half-vision centre; a series of transverse vertical sections through the brain in two cases of lesion of the half vision centre; perimeter charts showing the fields both for white and for colors in cases of central amblyopia (? tobacco amblyopia) and lead poisoning; and a plate showing the lesions of secondary syphilis. The consideration of changes in the fields of vision is continued in part second of volume second, the rest of the fasciculus being devoted to Asiatic cholera and to syphilis. The latter subject is illustrated by nine plates, of beautiful workmanship, and constituting real portraits of an abnormal condition most wide-reaching and disastrous in its effects. Anticholeraic inoculation, extensively tested upon animals and securing for them a period of immunity of four months and a half, is discussed with the most sanguine expectations. The operation is harmless to human beings, for over fifty persons have been inoculated, of French, Swiss, Russian, English, and American nationality. "The symptoms that it evoked were a rise of temperature, a local sensitiveness at the place of inoculation, and the formation of a transitory œdema at the same place. . . . The symptoms following the second inoculation were generally rather more marked, but of shorter duration. The whole recalls the sensation of a bad cold in the head, lasting one or two days." Its effect as a prevention of cholera awaits demonstration during an epidemic.

This atlas may justly be termed, as the author suggests, an illustrated treatise on clinical and systematic medicine. It should obtain recognition everywhere, especially among English-speaking races. The plates are beautiful. Though a striking feature, these, however, are not the most important part of an arduous and serious undertaking, involving great financial outlay. There is every reason to suppose that all succeeding fasciculi will equal the ones already issued. In this event, the atlas of clinical medicine will prove an excellent investment for the physician of wide mental horizon, who wishes to keep well in touch with modern medical thought.

Gonorrhœa. Being the Translation of Blennorrhœa of the Sexual Organs and its Complications. By Dr. Ernest Finger, Docent at the University of Vienna. Third edition. 8vo, pp. 324. New York: William Wood & Co. 1894.

This work, so well known to our German readers, has been translated into English from the third enlarged and revised German edition, and brings our knowledge of this important disease up to the latest information regarding its pathology and treatment. The subject is quite exhaustively treated, and the descriptions of the symptoms and complications are described in all their necessary minutiæ. The divisions are anatomical as well as pathological, while the clinical aspects of the latter are graphically presented and practically considered. The author, adopting the advanced views of the etiology of the affection, very properly claims that the infection is due to the gonococcus and is essentially specific in character, hence the foundations for successful treatment are based upon the destruction of the peculiar diplococcus, either by internal medication or topical application, or both. The rules for following out these respective methods are very clearly and logically given, and leave nothing to be desired for the earnest student in search of strict scientific methods for curing this common and troublesome affection. In view of the loose methods of treatment now employed, this work has a timely interest in directing study in the proper direction of fulfilling different indications, as they present themselves in the varied stages and the multifarious complications occurring in both sexes. The value of the book is otherwise enhanced by numerous excellent woodcuts and seven excellent full-page plates in colors It is a practical work from beginning to end, and will be duly appreciated accordingly.

Hospitals, Dispensaries, and Nursing. Papers and Discussions in the International Congress of Charities, Correction, and Philanthropy, Sec. III., held at Chicago, June 12–17, 1893. Compiled by John S. Billings, M.D., and Henry M. Hurd, M.D. Pp. 711. Baltimore: Johns Hopkins Press. 1894.

This work is really an encyclopædia in one volume, and contains a vast amount of information of all kinds. It is divided into six parts. In the first are given the papers read at the general sessions of the Congress. Five papers are printed in full.

In the second part are thirty-one papers read before the various section meetings. They cover the widest possible range of topics relating to the establishment and maintenance of hospitals.

The third part is devoted to nursing, and comprises twenty-nine papers.

The title of Part IV. is "Dispensaries." Only one paper is printed, that of Mr. C. C. Savage, President of Demilt Dispensary, of New York City, the substance of which has already been given in the Record.

Part V. comprises seven papers devoted to "First Aid to the Injured."

Part VI. discusses "Hospital Saturday and Sunday."

We have too long been accustomed to the scientific accuracy, in every undertaking, of the distinguished editors of this volume to express any surprise at the admirable manner in which their work has been accomplished. The Congress itself brought physicians and laymen into close association, and for that reason alone would have been a praiseworthy undertaking.

Naturally, in a work of this kind the papers are of a varying degree of excellence, but all are good. No physician who desires to have at hand a ready reference-book concerning hospitals, etc., should fail to secure this volume. It should be in every public library from Maine to Texas and from Oregon to the Gulf.

Combining Equivalents.—A western paper relates that a patient became seriously sick as the result of putting his own interpretation on the direction to "take every three hours as much as a ten cent piece would hold." In its stead he took as much as he could heap on a nickel every hour and a half. This reminds us of the man on shipboard who went for the preparation numbered 13, but finding it missing split the difference by combining numbers 6 and 7, with the result of proving the old-timed activity of the unlucky number.

Small-pox in Chicago.—The Chicago Commissioner of Health reports that during the year 1893 there were 140 cases of small pox in the city of Chicago. Cases occurred during every month of the year except March and May. Thirty-five cases occurred during November, and 66 during December. There was a total of 25 deaths, none of which occurred in any case that had been previously vaccinated. But few of the cases could be traced to their origin.

Society Reports.

ELEVENTH INTERNATIONAL MEDICAL CONGRESS.

Held in Rome, Italy, March 29, 30, and 31, and April 1, 2, 3, 4, and 5, 1894.

SECTION ON PRACTICAL MEDICINE.

Nitrate of Aconitine.—Dr. Tison, of Paris, read a paper on the therapeutic properties of this salt. He employs it dissolved in a mixture of glycerine, alcohol, and distilled water, in the proportion of gr. $\frac{1}{64}$ to the drachm. He has used this drug in about sixty cases of facial erysipelas, and regards it as the best known remedy for this affection, reducing the pain, preventing complications, and cutting short the attack. It is also of great value in certain forms of neuralgia, especially facial neuralgia. Neuralgias dependent upon chloro-anæmia are, however, better treated with exalgine. In many cases of laryngitis and aphonia due to an ordinary cold, the nitrate of aconitia is also beneficial. The drug may be given in maximum dose of $\frac{1}{64}$ grain a day, divided in ten doses. In pyretic conditions he has never observed any intolerance of the drug, but in afebrile states there is occasionally a little formication caused by the doses above mentioned, and in such case it is necessary to suspend the administration of the remedy. The menstruum of alcohol, glycerine, and water, so proportioned that the mixture has the specific gravity of distilled water, is useful for the exhibition of all the alkaloids.

Plasmodium Malariæ.—Dr. Marchiafava, of Rome, described the malarial parasite of summer-autumn fever, giving its life history, its various localizations, cerebral, intestinal, and general, and presented a sketch of the anatomico-pathological changes present in pernicious fevers, especially in the intestinal forms. He insisted especially upon the fact that the form of malarial parasite, described by him as the summer autumn variety, was alone active in causing pernicious fevers.

Malarial Anæmia.—Drs. Bignami and Dionisi, of Rome, read a paper on this subject in which they divided the post-malarial fevers into several groups, normoblastic and megaloblastic. From these are to be distinguished the anæmia due to atrophy of the medulla, and that accompanying malarial cachexia. Various hemolytic poisons give rise to blood changes, and the authors called attention to the points of difference and resemblance between these and the conditions of the blood found in post-malarial anæmia. The latter is the result of various lesions caused by the action of the malarial poisons in different viscera.

Nervous Lesions in Rabies.—Dr. Golgi, of Pavia, said he had often observed in animals dead of experimental rabies various alterations in the nuclei of the nerve-cells (swelling and chromatic changes), and also vacuolization and granular degeneration of the protoplasm. By means of his method of black staining he has found changes in form of the cell bodies, swelling and complex deformation of the nervous prolongations. He had also seen kariokineses of the epithelium of the vessels and of the neuroglia.

Rachitis and Infantile Convulsions.—Dr. Jules Comby, of Paris, read a paper on the relation between convulsions in infancy and rickets, of which the following are the conclusions: 1. Convulsions, both general (eclampsia) and local (spasm of the glottis) are of frequent occurrence in rachitic children who are predisposed by a neurotic inheritance. 2. Rachitis cannot in itself or in its osseous lesions, even when they affect the skull (craniotabes), account for the occurrence of these convulsive attacks. Indeed, these are seen in children free from craniotabes or any rachitic taint, and on the other hand very many children, the majority in fact, who are subject to extensive craniotabes and other pronounced symptoms of rickets, never have convulsions at all. 3. The explanation of these convulsions is to be sought elsewhere. The author regarded them as due to the digestive troubles so universally associated with rickets. In a word, he said, convulsions in rachitic children are due to an auto intoxication, the origin of which is in the digestive canal.

The Fungus of the Trichomycosis Nodosa.—Dr. Bergonzini, of Modena, said that as long ago as 1881 he had described an affection of the skin of the upper lip in which he had found spores vegetating on the cutaneous surface. A culture of these spores resulted in a filamentous mycelium, a description of which was communicated to the Medico-chirurgical Society of Modena and published in several medical journals. This year he had seen a precisely similar case, which he had studied by means of more accurate cultures and microscopical observations. He thought it was probable that the fungus discovered by him was the same as that described by Behrend in 1866, and by Juhel-Renoy in 1888, as belonging to the disease called by them "trichomycosis nodulosis." However, the fungus cannot be called by the name which Behrend proposed, namely "Trichosporon ovoide." It is a fungus of the order sphomiceti, of the family Mucidinææ, of the sub-faimly Amerosporæ, of the genus Monilia, which the author proposed to call "Monilia trichophila."

Localization of the Reflexes.—Dr. Ernest Jendrássik, of Buda-Pesth, presented a communication on this subject. On the basis of clinical symptoms and the results of experimental investigation, he divided the reflexes into certain groups, pretty sharply defined one from the other by their various modes of production, their progress, and the modifications occurring in them under certain circumstances. These groups were: 1. (*a*) Physiological, the phenomena known as "deep reflexes;" (*b*), pathological, reflex bending, less often extension, of the lower extremities, pseudo patellar reflex. 2. The skin, eye-lid-, pharynx-, anal-reflexes and the like. 3. Sneezing, vomiting, coughing, the reflex activity of the bladder, rectum, genitals, etc. 4. Vaso-motor reflexes, to which also belong the pupil-reflex. These several groups correspond to varied localizations: the first group belongs to the spinal reflexes, the second to the cortical reflexes, and the reflexes of the third group have their centres in the cord, but yet are controlled from the brain.

Syphilitic Tabes.—Dr. Adamkiewitz, of Vienna, said that when it was first shown that locomotor ataxia was often of syphilitic origin, the hope was expressed that the disease might be curable by specific treatment; but this hope had not been realized, and there is now a very general scepticism as to the value of such treatment. The speaker had, however, had several cases a very careful study of which had led him to the belief that there is a special form of tabes having certain characteristic symptoms and a specially defined clinical course, which is positively curable by antisyphilitic treatment, provided it be instituted at an early period.

The symptoms of this curable form of locomotor ataxia are: Ataxic paresis with loss of the tendon reflexes, paresis in the distribution of certain cerebral nerves, tabetic paræsthesia without objective disturbances of sensibility, and pain especially on pressure in the lumbar region. The clinical course of the disease is characterized by a rapid advance of the paresis of the lower extremities into complete paralysis, by ascent of this paralysis up to the lower part of the cervical spine, and, when the antisyphilitic treatment is early begun and energetically carried out, by a final complete restoration to health. The duration of the disease, when so treated, is three or four months. The most important clinical symptoms of the disease—ataxia and motor paresis—point to an involvement of the pyramidal tract as well as of the posterior columns, and the fact of a cure by means of iodides and mercury to functional disturbance resulting from a not irreparable process. There can be question here of syphilitic products only which appear under the form of obliterating endarteritis and syphilitic pachymeningitis.

The influence of syphilitic disease of the vessels on the

functions of the anterior and posterior columns is most satisfactorily explained by the results of the author's studies, elsewhere published, on the vascular supply of the spinal cord.

When, through lack of proper specific treatment, there is no resolution of the syphilitic products in the spinal cord, the diseased vessels become obliterated, and the parts of the cord supplied by them become sclerosed. In this case, similarly to what the author has shown to occur in tuberculous pachymeningitis, wedge-shaped lesions are formed in the substance of the cord in which the nerves are destroyed. The author has called this lesion, which results in incurable spinal paralysis, infarct of the cord.

The general belief that syphilitic vascular lesions of the brain only, and not of the spinal cord, are curable is disproved, the speaker said, by the observation upon which he had based his paper.

The Etiology of Tabes.—Dr. Alessandro Borgherini, of Padua, presented a communication on this subject in which he said that tabes is essentially a systematic affection; its pathogenesis is to be sought for in a special morbid predisposition of certain elementary spinal tracts. The various etiological factors in connection with this disease act only secondarily. Syphilis, indeed, has a certain causal relation to locomotor ataxia, but the idea that it is the sole cause of the affection is an exaggerated one. Some statistics recently collected in Italy by the author, with the aid of many of his colleagues, showed that hardly thirty per cent. of those suffering from tabes were syphilitic; among the other causes shown were rheumatism, mental and bodily overwork, venereal excesses, etc., and in some no active cause could be discovered. Notes of a neuropathic taint in the family history of those suffering from tabes were by no means rare.

Ophthalmoplegia and Superior Bulbar Paralysis.—Dr. Alessandro Marina, of Trieste, read a paper with this title, of which the following were the conclusions: In cases of tumor of the corpora quadrigemina a lesion of special systems of fibres does not produce simple tremor, but rather tremor combined with ataxia. The integrity of the endo-ocular muscles is not a sufficient sign upon which to base a diagnosis of external unilateral ophthalmoplegia of nuclear origin. Superior bulbar paralysis may be diagnosticated with certainty when ophthalmoplegia is joined to bulbar paralysis and poliomyelitis; in tabes the process may be peripheral, but is generally mixed. The close relationship between tabes and syphilis is proved also by those cases in which microscopical examination reveals no characteristic signs of a syphilitic process, while during life the nervous phenomena were clearly associated with a relapse of syphilis. Acute superior poliencephalitis, which may occur independently of alcoholism, is found more often with acute infantile encephalitis than with chronic external ophthalmoplegia, and is due more probably to lesions of the nuclei of the central gray matter than to those of the fibres connecting this central gray matter with the cortex. Recurring paralysis of the motor oculi muscles may also be the result of a recurring neuritis.

The Modifications of Form of Cancerous Cells and Nuclei which may be Mistaken for Parasites.—Dr. Cornil, of Paris, presented an interesting paper on this subject. Cancerous tissue, he said, always shows a number of cells in process of indirect division. The division of the nucleus into two, three, or four parts results sometimes in the formation of several cells, sometimes in the production of two or three nuclei which remain inclosed in the same cell. The indirect multipolar division, with five, six, or seven stellar figures, observed as often in cancerous tissue as in the large cells of bone marrow, may also give birth to several nuclei in the same cell.

The large nuclei of these giant cells are, in the quiescent state, just as in the case of the giant cells of the bone marrow, very varied in form, mallet shaped, sinuous, fringed, branching, crown-shaped, irregularly serpentine, cogged, and in places clusters of roundish secondary nuclei are seen. In the latter case these secondary nuclei contain but little chromatic substance. They separate themselves from the principal mass and become scattered about in the cellular protoplasm, looking like little cystic bodies. But all these swollen nuclei which have become œdematous, whatever their shape, contain the same substances as the ovoid nuclei of the cancer cells in a state of inaction or of indirect division.

The substances contained in the nucleus of a cancer cell, as in that of an epithelial cell, are: 1, a liquid; 2, a solid substance in the shape of granules or filaments, nucleine; 3, another solid substance, also in the form of granules or filaments, paranucleine. These two substances are isolated and differentiated in the nucleus by means of the affinity which they have, the first for the basic colors, the second for acid colors. In preparations made by a special process by M. Frenkel the nucleine is stained an intense blue, the paranucleine a bright red. In the small ovoid nuclei of the quiescent cancer cells the blue filaments and fine granulations make up the nuclear framework and envelope; these blue filaments and granulations are crowded pretty closely together, yet it is possible to see here and there a granule of paranucleine stained red. In the neighboring cellules of the same size as the preceding or larger the nucleus, although remaining ovoid or more nearly spherical in shape, is larger and contains more fluid, and these two kinds of filaments and granules are more readily seen. The blue granules or filaments of nucleine are found at the periphery, while the red paranucleine occupies the cerebral portion, forming one or more round or slightly elongated drops. When the nucleus is spherical we find in its centre one large globule of red paranucleine often surrounded by a thin film of blue nucleine. In the arborescent, fringed, or lobulated nuclei the arrangement of these two substances is the same.

During the first stages of growth of the nuclei the nucleine breaks up into roundish or ovoid granulations, and at the same time the paranucleine increases and divides into granules and droplets. This destruction of the two substances proceeds in a most evident manner throughout all the stages of mitosis. The nucleine, in its filaments and granules in the equatorial, and after segmentation in the polar plaques, is distinguished by its beautiful blue color from the filaments of paranucleine and granules of the same substance, which are of a bright red color and constitute the polar rays. All the details of nuclear mitosis, separated from the cellular protoplasm by a clear zone, are seen here most distinctly. After the division of the nucleus and of the cell has taken place, the twin nuclei still remain for a time united by filaments of paranucleine.

Alongside of these giant mitoses we often see in the same cancerous growth alveolus cells of the same size containing, in a state of repose, one or more large nuclei, branching, fringed, modulated, or clustered. Whatever may be the arrangement and the number of these nuclei, they always have, as said above, filaments and granules of nucleine at their periphery and one or several central globules of paranucleine. As these large nuclei, of various shapes and often œdematous, are found alongside the multipolar giant mitoses, it is natural to suppose that they are due to indirect division of the nuclei, which has not gone the extent of division of the cellular protoplasm. These to deformed nuclei have been described as parasitic bodies by Foà, Soudakewitch, Ruffer, and others. The descriptions and the drawings given by these observers correspond exactly with those published by the author in 1881. From the results of the double staining of the nucleine and paranucleine of the nuclei in a state of repose, and of kariokinetic growth, and of the other misshaped nuclei, Dr. Cornil maintained that these supposed parasites were merely nuclei poor in nucleine and containing in their centre one or more droplets or corpuscles of paranucleine. That which characterizes especially the cancerous cellules is the enormous number of mitoses, the exag-

gerated movement of the nucleine and paranucleine of their nuclei. The kariokinetic figures are far from presenting here the same regularity as in normal tissues, and they are often irregular, asymmetrical, or wholly abnormal.

Among these anomalies one of the most curious, described by the speaker in 1891, is the isolated development of a nucleus dependent upon a giant mitosis, the nucleus arriving at maturity while the rest of the kariokinetic filament is evolved more slowly. From this results the development of a nucleus, and even of a cell, inclosed in the protoplasm of a giant cell, the principal nucleus of which may become œdematous or may assume an arborescent or other shape.

The wandering white cells found in great numbers in the rapidly growing portions of cancerous tissue, and which supply them with nutriment, have also been described as parasitic.

Those who hold to the parasitic nature of cancer base their belief solely on the morphology of the cells—an insufficient ground. The bodies described by them as parasites are, the author maintained, nothing but modified nuclei and cells resulting from the changes above described.

A Case of Syringomyelia Complicating Leprosy.—Dr. Sousa Martins, of Lisbon, related a case of this kind, and formulated, as a result of his observations and studies, the following conclusions: 1. We cannot admit syringomyelia as a nosological entity. 2. Syringomyelia is merely a condition and not a disease, similar in a certain sense to the cavernous affections of the lungs which we might justly call "syringopneumia." 3. The condition called syringomyelia may be present in various diseases. 4. Leprosy is one of these diseases.

The Determination of the Quantity of Heat Given off from Different Portions of the Body.—Dr. Curzio Bergonzini, of Modena, said that he used a mercurial thermometer with spherical bulb, of which the weight of the glass of the bulb and of the mercury was noted, and also the volume and circumference of the bulb itself. This instrument being exposed to a source of heat for a determinate time, we can easily determine by it the amount of heat it has absorbed per square centimetre of its surface in the given unit of time, allowance being made for the specific heat of the glass and of the mercury. Such a thermometer applied to a region of the body which can completely envelop the surface of the bulb (the axilla, popliteal space, hand, etc.) will indicate how much heat it has absorbed in a given time from contact with a surface of skin equal to that of the bulb. The figures thus obtained will evidently be equal to those representing the heat evolved in the same time from the cutaneous surface of the explored region, and we can thus determine how much heat is given off per minute or per hour from a given portion of the surface of the body. By this means the author has been able not only to calculate the maximum and minimum of heat units given off from various parts of the body under diverse conditions, but also to determine the variations in the emission of heat in fever, in different seasons of the year, at different ages, and in diseases of various kinds.

Treatment of Psoriasis.—Dr. Cerchez, of Berlad, Roumania, read a short paper advocating the use of iodide of potassium in large doses as the most efficacious remedy for psoriasis, provided the patients had no idiosyncrasy contra-indicating its employment, and provided also that the uropoëtic organs were in a healthy state.

Hypodermic Medication.—Dr. J. Roussel, of Geneva, presented a communication reviewing his various experiments and publications concerning the subcutaneous administration of remedies. The hypodermic pharmacopœia is sufficient to-day, he said, to meet all therapeutic indications. This method, by which remedies are passed at once into the circulation without running the hazards of digestion, is all powerful in dyscrasiæ of the blood, whether simple or infectious, often aborting them, curing them more speedily and certainly than other methods, and preventing their degenerative sequelæ. A preventive antiseptic injection is useful in the beginning of morbid processes, and even if it does not succeed in abating them it is never harmful. He contended that the time was at hand when direct circulatory therapeutics, the transfusion or injection of accurately dosed, assimilable, and aseptic remedies, would alone be deemed worthy of the attention of practical physicians whose aim is to prevent and cure disease without doing injury.

Mycodermic Medication.—Dr. Backer, of Paris, presented a paper on a therapeutic method which he called the "mycodermic," consisting in the hypodermic injection of yeast fungus. This fungus, he said, continued to live in the tissues and destroyed pathogenic bacteria by a process of phagocytosis. He had tried the method in a large number of cases of tuberculosis, and claimed to have cured ninety per cent. of cases in the earlier stages, and sixty-five per cent. in phthisis of the second degree. He had made nearly five thousand injections, and had never seen suppuration or any other injurious effects from them.

Serum Treatment of Tuberculosis.—Dr. Bernheim, of Paris, read a communication on this subject. He said he did not pretend to cure all cases by the injection of blood serum from an immune animal, yet the results obtained in incipient phthisis were most encouraging. He had so treated about three hundred cases in private and hospital practice, with the result of obtaining at least a temporary cure, the time which had elapsed being too short to permit him to assert that the cure was permanent and final. He felt himself justified, however, in claiming that immunized serum has a true vaccinal action in tuberculosis.

Heredity and Contagion of Tuberculosis.—Dr. Bernheim presented another communication with this title. He said that there was no such thing as a genuine inheritance of tuberculosis, the disease being always acquired by contagion, and that therefore all children of tuberculous parents should be immediately isolated and removed from the ever present source of contagion in their own parents. Physicians should recognize this necessity, as had already the veterinarians. They might thus save the lives of many children who are the more easily infected from having been conceived under unfavorable conditions.

Lysol in Typhoid Fever.—Dr. Tison, of Paris, read a paper on lysol, which he regards as a perfect general, and especially intestinal, antiseptic. Its employment gives excellent results in eruptive fevers, but more particularly in typhoid fever. It is also a very useful remedy in diarrhœa. It may be employed externally or internally according to the effect which it is desired to obtain, and however used its effects are admirable.

Treatment of Pernicious Anæmia.—Dr. F. W. Warfinge, of Stockholm, read a paper on this subject, giving the results of the treatment of this affection and of leukæmia and pseudo-leukæmia by arsenic in the Sabbetsberg Hospital, during the years 1887–1893. The success obtained by this method was, in the speaker's opinion, phenomenal.

Transfusion.—Dr. H. v. Ziemssen, of Munich, read a paper on this subject. The intra-venous transfusion of undefibrinated blood is, he held, a perfectly harmless procedure in skilful hands, but for the general run of practitioners who have not had sufficient experience, the subcutaneous injection of blood is to be preferred, as it offers fewer technical difficulties. The immediate effect of intra-venous transfusion is a heightened color and an increase in strength, with which, however, the increase in red blood-globules and in the proportion of hæmoglobine is not always proportionate. In the treatment of chronic anæmia, frequent transfusions of small doses (three to four ounces) appear to be more effectual than a single injection of a larger quantity.

Twelve Years of Sanitation in the Province of Ontario, Dominion of Canada.—Dr. E. E. Kitchen, of St. George, Canada, member of the Provincial Board of

Health, presented a communication with this title. In opening the paper the reader gave a few of the laws enacted on account of the several visitations of cholera to this country during the century, and opened the paper proper with the fact that the Provincial Board of Health of Ontario was established by law in 1882, and this was the commencement of systematized sanitation. The Board consists of seven members, including a secretary, who is the provincial health officer. Their meetings are quarterly, although special ones may be called; the duties of the Board were defined as by statute. The many laws enacted for sanitary purposes and their amendments were explained, as well as the formation of local Boards of Health and the mode of operating them. During 1882 and 1883 circulars were sent out to municipal councils, asking if such local boards were formed, when it was found that only fifty boards had been formed in forty counties. This to a great extent caused the Public Health Act to be enacted, and this made the formation of local boards compulsory, as well as placed on the board a number of rate-payers. This caused such a great improvement that during the half of the year 1885 there were formed 184 local boards in 447 townships, and 180 boards in 203 cities, towns, and villages. This increased organization made itself felt in the subsequent early visitation of small-pox. Shortly after this it was found that there were in 600 municipalities 563 local boards, 283 medical health officers, and 160 sanitary inspectors. In 1886 the number of boards had increased to 610. From time to time various regulations, etc., have been made, until the system is wellnigh perfected. Scarlet fever, diphtheria, etc., are now under such strict regulations at home and at school that it is generally stamped out upon its first appearance. Reference was made to regulations of dairies, creameries, and the milk-supply, and many other matters vital to a country. The Board has been doing very satisfactory work with tuberculin as a diagnostician of tuberculosis in cattle. Very many other interesting facts were discussed, and this very succinct and readable paper closed by a cursory reference to the fine state in which the quarantine service of Canada is at present.

SECTION ON SURGERY.

Perineal Lithotrity.—Mr. Reginald Harrison, of London, described a method of performing perineal lithotrity employed by him in a number of cases of vesical calculus. It consisted in an incision through the membranous urethra, rapidly breaking the stone with crushing forceps, and washing out the fragments. This operation was applicable in some cases of stone which were complicated with vesical disease and growths in the bladder, and connected with the prostate. In all other cases ordinary lithotrity was advised by the speaker. He had employed the method described in fourteen cases out of four hundred operations for stone in the male bladder.

Floating Kidney.—Dr. Tricome, of Padua, operates for the fixation of wandering kidney by fixation to the quadratus lumborum through a double series of sutures. The deep layer acts in way of fixation, attaching the organ to the margin of the wound made in the muscles, the superficial layer closing the external wound. He had operated by this method in twenty-six cases. Of these twenty-two were entirely relieved of all the symptoms previously complained of, one was greatly benefited though not cured, and one died five months after the operation. The remaining two were lost sight of.

Extirpation of the Kidney.—Dr. Durante, of Rome, performed an operation for cancer of the kidney, at his clinic in the Via Garibaldi, in the presence of many members of the Surgical Section. The operation for the extirpation of the diseased organ occupied about half an hour from the beginning of anæsthetization to the time the patient was taken back to the ward.

Pleurotomy.—Dr. Bozzini, of Italy, reported two cases of this operation for the relief of suppurative pleurisy. In the first case the pleurotomy was followed by a partial resection of the lower lobe of the left lung. The second case was complicated by suppurative perihepatitis and subsequent biliary fistula. In both cases a perfect cure of the empyema was obtained.

A Local Anæsthetic.—Dr. Tison, of Paris, reported on a new local anæsthetic which he called "coryl." It was a mixture of chloride of methyl and chloride of ethyl. When applied to the skin or mucous membranes the temperature of the tissues is reduced to about the freezing-point, low enough to cause complete anæsthesia, but not so low as to give rise to the formation of eschars. This substance is much more efficient than the other refrigerant agents, and much safer than the medicinal anæsthetics such as cocaine. Coryl was the discovery of M. Joubert, of Paris.

Pyogenic Diseases of the Brain.—Dr. Macewen, of Glasgow, read a paper with this title, of which the following were the conclusions: 1. All abscesses of the brain are formed secondarily to a primary focus of infectious disease located elsewhere. 2. The chief infectious foci are formed in connection with middle-ear disease. 3. Abscesses of the brain coming from this source are generally in direct contact with the seat of the middle-ear disease. 4. Such abscesses are usually reached most easily through the mastoid antrum. 5. The latter is best reached by an incision through the supra-mental triangle, by which means the whole tegmen antri and tegmen tympani may be exposed. 6. The whole infectious tract must be removed, after which the skull should be trephined over the temporo-sphenoidal lobe of the brain.

Researches in Cranio-encephalic Topography.—Dr. E. Masse, of Bordeaux, said that he had been able to locate, by auto-impression, the sulci of Sylvius and Rolando, and had by mensuration determined a series of fractional numbers by means of which he was able to make the operation of trepanning mathematically exact.

Cerebral Surgery.—Dr. P. Postempski, of Rome, reported twenty cases of craniectomy, and formulated a number of conclusions derived from a study of them. He held that great exactness in craniotopography is unnecessary, all that is needed being to make a sufficiently large opening. Surgical intervention is useless in hydrocephalus and microcephalus, and the same is true in cases of ordinary epilepsy.

Resection of the Trigeminus at its Point of Emergence from the Bridge.—Dr. A. D'Antona, of Naples, reported a number of experimental resections of the trigeminal nerve, and made some observations deduced from the results of these operations. Tissues deprived of innervation, he said, became vulnerable because their nutritive energy and organic constitution are weakened. Atrophy consequently sets in. In the eye the conjunctiva becomes softened in patches and breaks down, deep corneal ulcerations resulting.

Resection of the Vertebral Arches.—Dr. A. Caselli, of Genoa, read a paper on temporary resection of the posterior vertebral arches as an explorative and curative method in various cases of injury to the meninges and cord. He proposed the operation of specotomy by means of temporary laminectomy. His experiments proved that perfect union took place after the operation without the production of deforming callus or the intercurrence of any complicating accidents. The speaker also reported a case of resection of the third, fourth, and fifth dorsal vertebræ, for the relief of paraplegia caused by slow compression of the cord from exostosis and pachymeningitis. He devised a special rachiotome, which was exhibited at the meeting, for this operation. The exostosis was removed and the patient made a perfect recovery.

Trephining for Epilepsy.—Dr. J. Lucas-Championnière, of Paris, read a paper based upon the clinical study of sixty-four cases of trepanation of the skull. The good results of this operation may be observed, he said, when it is performed for the relief of renal epilepsy, and of certain forms of traumatic meningo-encephalitis ac-

companied by severe pain in the head, vertigo, and other dangerous symptoms. In cases of Jacksonian epilepsy, however, the indications for trephining are not sufficient to justify its performance, and the practical results of the operation are not at all satisfactory.

Provisional Costotomy in Acute Pleuritic Exudations.—Dr. Z. Lamfirescu, of Jassy (Roumania), said that the title of his paper indicated sufficiently the object of the temporary resection of the ribs, which he had first practised in 1877. The operation might also be undertaken in cases of purulent exudation in which pleural adhesions had not yet taken place.

The operation is performed in the following manner: The patient lies in a semi-reclining position, resting on the side opposite to that on which the operation is to be performed. The anæsthetic is pushed only to the stage of analgesia, and for this purpose ether is employed by preference. The ribs are counted from below upward, and in the space between the sixth and seventh ribs a line is marked by the dermographic pencil, which is crossed by a perpendicular line at a point indicated by the operator; from this last the distance in front and behind to which it is desired to resect the rib is measured off and marked by other vertical lines. An incision is made along the intercostal line between the two extremities previously marked, down to the internal intercostal muscles, and then the skin only is incised along these two boundary lines to a point just above the upper edge of the rib which is to be excised. Now the costotome is inserted at the point marked by one of the vertical lines, one blade on each side of the rib, pushed down until the points have penetrated the pleura, and then the rib and soft parts, including the pleura, are cut through by the instrument. The operation is repeated on the opposite vertical line. In this way a flap embracing the pleura, bone, and superimposed soft parts is made and thrown back. The artery must be ligated or twisted.

The suppurating cavity is now washed out by means of antiseptic irrigations made through a fenestrated rubber drainage-tube curved on itself, so as to permit of a double current. The whole side of the thorax is then enveloped in a thick layer of carbolized wadding retained by a roller bandage.

After the operation the temperature is taken regularly, and if it is observed to rise, the dressing is removed and the cavity washed out through the drainage-tube until the liquid flows clear. The dressing is then to be reapplied. The number of irrigations to be made depends upon the temperature, and when the latter has been normal for ten or fifteen days the wound may be closed, the extremities of the resected rib being freshened, and sutured by silk, strengthened, if necessary, by silver wire. The soft parts are sutured with silk or catgut. A drainage-tube of very small calibre is left in the wound for a few days, and when it is found that the pleura secretes no more, the opening is definitely closed. After the osseous suture has been made that side of the thorax is strapped with long strips of adhesive plaster. The orifice of the drainage-tube is covered with carbolized or iodoform cotton, and the whole retained in position by a body bandage. The dressing is removed after a certain period of time—the length of which depends upon the circumstances in each individual case, but never under forty days.

Treatment of Serous and Purulent Pleuritic Exudations.—Drs. Demosthen and Calinescu, of Bucharest, presented a report based upon the records of fifty cases of pleurisy treated surgically in the Roumanian Army Hospital at Bucharest. In twelve cases the exudation was serous, in one sero-sanguinolent, and in thirty-seven purulent. The serous and sero-sanguinolent cases were treated by aspiration, practised from one to three times on the same individual, and by appropriate general treatment. The management of the purulent cases varied according to the nature and amount of the fluid, the capacity of the pleural cavity, the state of the lungs and the pleura, the patient's general condition, the results of a previous intervention, etc. There were five aspirations made either in the way of diagnosis or because the general health of the patient did not warrant at the time a more radical operation, twelve simple pleurotomies with drainage, nineteen pleurotomies with resection of one rib, ten with resection of two ribs, and four Estlander operations. The authors resorted to simple pleurotomy when the intercostal space was wide enough to permit the easy insertion of a drainage-tube, and to pleurotomy with the resection of one or two ribs when, as is often the case, the space was too narrow to accommodate the drainage-tube. Antiseptic lavage of the pleural cavity was practised regularly as long as suppuration continued, and this because it was found to conduce to a lowering of the temperature, suppression of the suppurative process, and reduction of the dangers of infection. The authors never had to regret any of the accidents resulting from this procedure, which have been observed by other physicians.

In performing the Estlander-Liétévant operation they invariably resected the pleura from the thoracic wall throughout the whole extent of the field of suppuration, because this membrane, sclerosed and rigid as it is, opposes almost as great an obstacle to the retraction of the chest-walls as do the ribs themselves. They found no cases in which Quénu's procedure (immobilization of a portion of the costal skeleton) was indicated. Fever offers no contra indication to surgical intervention, nor does pulmonary tuberculosis, unless marked cachexia be present.

As to the results of treatment, the authors never saw a cure of purulent exudation from medical means. Of serous exudations, almost all chronic, they had ten definite cases, ten cases of improvement with the persistence of small sinuses which did not prevent the patients from attending to their ordinary duties, and nine deaths from intercurrent disease, chiefly tuberculosis in other organs.

The duration of the disease varied from fifty days to two years. As a rule, especially in the purulent cases, the recovery is slow, yet in some cases surgical intervention was followed by a veritable resurrection, and from poor, emaciated, cachectic subjects the patients became rapidly fat and healthy-looking.

In conclusion, the authors urged the practice of surgical measures in all cases of suppurative pleurisy, and the sooner the better, for the results were always the more striking the nearer the onset of the disease the treatment was instituted.

Discussion on M. Ollier's Essay on Osteoplastic Operations.—Dr. Thomas H. Manley, of New York, in discussing a paper by Dr. Ollier on this subject, said that it afforded him great pleasure to listen to the contribution of M. Ollier, who is now regarded as one of the most eminent living authorities on this line of surgery. The greater part of the papers of the morning had especially dwelt on operations for pathological lesions of bones; but he would ask attention for a moment to the surgical therapy of osseous traumatisms of that class so fully set forth by Dr. Link, of Indiana.

One of the most common and serious types of bone traumatism, which involves the extremities and often threatens a limb's vitality, is compound comminuted fracture. He would ask the members to bear in mind the fact that the time of treatment appropriate for even the most grave types of compound fractures, in vogue twenty-five years ago, would not be accepted in our times. The achievements of Lister had enabled us to effectually stamp out infection, the experiments and observations of Ollier and others have opened the way to such osteoplastic operation, on disorganized bone from physical violence, as will enable us to now preserve very much of what was formerly destroyed.

A most sweeping revolution had been wrought on the subject of the severance of a limb, and the time had now come when a primary amputation, in civil life, should never be entertained, under any circumstances, unless the physical force employed had totally destroyed all

the parts beyond the site of injury. Of late years resection has been largely utilized as a substitute for amputation, in a large number of cases of pathological lesions of bone. Resection, instituted at the right time by the surgeon, would obviate the necessity for amputation in a large number of traumatisms. But to osteoplasty we must turn for such aid as will render our efforts successful in this direction.

Uterine Drainage by Catgut.—Dr. Schmeltz, of Nice, read a paper on this subject in which he maintained that a certain number of diseases of the uterus and its adnexa could be cured by catgut drainage, without having recourse to bloody operations. In 1883 Schwartz proposed drainage by spun glass fibres and caoutchouc, but the former was hardly practicable, and the latter necessitated a previous dilatation of the os. The catgut drainage proposed by the author was, on the contrary, easy of application, not requiring dilatation of the uterus, and perfectly aseptic. The presence of the drain does not in the least interfere with the proper performance of the menstrual functions, and it seldom causes pain or inconvenience of any sort. The operator had employed this method successfully in metritis, salpingitis, uterine deviation, amenorrhœa, dysmenorrhœa, and arteria of the neck of the uterus. The only contra indication is acute inflammation of the womb or its adnexa, and acute perimetritis. In such cases the presence of the drain might increase the existing inflammation.

Exploratory Laparotomy.—Dr. François Villard, of Bordeaux, reported six cases of exploratory laparotomy, and presented certain conclusions concerning the operation, which he said was indicated in the following cases: 1, For purposes of diagnosis; 2, for the cure of tubercular peritonitis and to break up pelvic adhesions; 3, to favor the resorption of certain serous effusions.

Tubal Pregnaney.—Dr. Villard also presented the report of a case of extra-uterine (tubal) pregnancy, in which he had performed laparotomy at the twelfth month, removing the tube and the product of gestation. The woman made a perfect recovery.

A Report on Symphyseotomy.—Dr. Leopold, of Dresden, said that symphyseotomy carried out on the lines laid down by Morisani has given such brilliant results that it must now be regarded as a most valuable addition to the therapeutic measures at our command. Nevertheless, it never can and never ought to become generalized or to be substituted, in the hands of the general practitioner, for perforation or turning, for its dangers are great and not to be underestimated.

In the case of primiparæ, the operation should be avoided if possible.

A woman on whom symphyseotomy has been performed should be kept under observation for a long period, and her condition at the end of one or two years should be made the subject of a careful report.

The occurrence of hemorrhage and injury to the vagina during the operation calls for special attention, for the management of such complications is often as difficult as the entire after-treatment in simple cases.

Symphyseotomy is indicated in preference to perforation of a living child in cases of narrow pelvis in which the conjugata vera measures from six or six and one-half to seven and one-half centimetres. Such cases should be operated upon in a hospital. If, however, in a case of narrow pelvis of this kind the practising physician is forced to manage the labor himself and to assume alone the entire responsibility of the issue, he should not undertake to perform symphyseotomy or the Cæsarean operation, but rather, when all other measures have proved of no avail, proceed at once to perforation of the living child, consoling himself with the knowledge that he has done the best he could—preserved the life of the mother.

In cases of narrow pelvis with a conjugata vera measuring down to 7 ctm., if the woman comes under observation at a sufficiently early period, premature delivery should be induced. If the case is not seen until late in the pregnancy or at the beginning of labor, complete dilatation of the os, with the bag of waters still unbroken, must be effected, and then normal delivery in Walcher's position be awaited. If spontaneous delivery does not then occur a success may often be obtained, in cases of flat pelvis with a conjugate of 7 ctm., or of generally contracted pelvis with a conjugata of 7½ ctm., by version, the os being fully dilated, the bag of waters unbroken, and the woman in Walcher's position. It is only very seldom, when all the special conditions are most suitable, and when version and the application of the high forceps give no hope of success, that we should resort to symphyseotomy in this latter group of pelvic deformities.

CONGRESS NOTES.

Two Thousand Ladies were registered as associate members of the Congress. Forty-six ladies, physicians, were registered as active members.

Sanitary Legislation in Italy.—Dr. Pagliani had printed in French for general distribution a pamphlet containing an account of recent legislation on sanitary matters in Italy, together with a description of all the scientific institutes under the direction of the Bureau of Public Health in the country. In an appendix was the text of all laws relating to sanitation and public hygiene.

The Illumination of the Forum, Palatine Hill, and Colosseum was very beautiful and carried out with much taste and skill. The grim old ruins looked strange but picturesque in the vari-colored lights.

The Garden Party at the Quirinal was hardly a Congress affair, though said to be given in its honor. The majority of those present were Italian officials, non-medical, foreign ambassadors and their families, and members of the ladies' entertainment committee. Only those foreign ladies were bidden who had been previously presented at court, and many prominent members of the Congress who were themselves invited remained away because their wives had been ignored Nevertheless there was a fair sprinkling of doctors and their wives among the guests.

The Archæological Section of the Medico-hygienic Exhibition was of great interest. It consisted mainly of exhibits from the museums of Rome and Naples—books, medals, instruments, engravings, statues, designs, urns, inscriptions, and votive offerings from the temples of Esculapius, Minerva, Diana, etc., by means of which one could follow the history of medicine in Rome from the earliest times down to the beginning of the last century.

Letter from Sir Joseph Lister.—Over the portal of the surgical pavilion at the Polyclinic is a high relief representing an operation at which Sir Joseph Lister is demonstrating the principles of antiseptic surgery. It is to this that he referred in the following letter, sent to the president on the opening day of the Congress:

"12 Park Crescent, Portland Place, London.

"Most Illustrious Professor: After the great honor which your classic city has done me, on the proposal of Professor Durante, by adorning with my effigy your new Surgical Clinic, it would naturally be not only a duty but a great pleasure for me to be present at the Congress over which you will preside, and to return personally my best thanks, while paying you the homage which is due to your merits. But the terrible shock which I have undergone through the loss of my beloved wife has deprived me of all courage for such an enterprise.

"Therefore, dear Mr. Baccelli, please accept my excuses, and at the same time my best congratulations for the honor done to us by your sovereign, who has entrusted you with the Ministry of Public Instruction.

"My heart will be with you in the Congress, for which I offer the most heartfelt wishes of a brilliant success.

"Your friend and admirer,

"Joseph Lister."

The Best Ordered Section was that on Military Medicine and Surgery. The members were accustomed to discipline and obeyed without protest the slightest command of the presiding officer. In consequence of this everything proceeded regularly and quickly, and almost every paper on the programme was read and fully discussed, yet the members had plenty of time to visit the military hospitals and barracks and to attend the general sessions if they so desired.

The Official Journal was an absurd affair, containing almost no information, and that usually misleading. The English of it was ridiculous and insulting to the members speaking that language, much of it being absolutely unintelligible, and it was only by reading the French or Italian column that one could gather the sense of what the editor meant to convey to his readers.

Professor Virchow's Speech.—The following is the report of Virchow's address at the inaugural session, as given in the *Official Journal* of the following day:

"The Professor Virchow, President of the last Congress, explaine the reasons that have decided the Physicians that in 1890 were reunited at Berlin, to choice Rom, as six of the XIth International Congress.

"The Orator said, that in this manner they have intended to make homage to the ancients tradictions. He exprime the desire that the Congress, can contribute to elevatad the morals aspirations, the ties of the friendsip of all countries, so that the fraternal place that must approch all the civilited Nations."

After the conclusion of this address, the *Journal* continues: "Mrs. The Delegates whom names are the following, have taken the word in order, to give the welcome to their Compatriots."

The International Congress of Hygiene and Demography.—The following telegram was received on the day of inauguration:

"Budapesth, March 28, 1894.

"In the name of the Executive Committee of the Eighth International Congress of Hygiene and Demography held in Budapesth, we cordially greet the Eleventh International Congress of Medicine on the occasion of its inauguration and wish it the greatest success in the interest of our science.

"Professor Joseph Fodor, *President.*
"Professor Calman Müller, *Secretary-General.*"

The Medal.—In addition to the membership card and rosette each person received a bronze medal about the size of a half-dollar. On one side was the legend: "XIth Congresso Medico Internazionale Roma, MDCCCXCIV." On the other was a reproduction of a medal struck in the time of the Emperor Antoninus, recalling an embassy sent to Greece in the year 291 B.C., after a consultation of the Sibylline books, in order to bring back the serpent of Esculapius from Epidaurus to stay the plague that was devastating Rome. The relief on the medal represents the river god Tiber half rising out of the water and extending his hand to receive the serpent at its arrival at the temple of the god of health, erected on the Insula Tiberina. The trireme bringing the serpent is seen appearing beneath one of the arches of the Fabrician (now the Quattro Capi) Bridge.

A Monument to Malpighi.—Subscription lists were opened in all the sections for contributions to a monument to the memory of Marcello Malpighi, to be erected in Crevalcore. A considerable sum was obtained for this purpose from the Italian and foreign members.

A Section of Medical Journalism.—Dr. Dobrzycki, of Warsaw, read a paper proposing that at future congresses a section of medical journalism be established, in which the needs and duties of this important profession might be discussed, and in which the representatives of the medical press throughout the world might obtain all necessary information. The need of such a section was never more apparent than at Rome, where the facilities for gathering news of interest to the medical profession were so exceptionally meagre.

An Anglo-American Reception was given on Saturday evening at the Grand Hotel by Mr. Burroughs, of London. All members of the Congress from America, England, and the Colonies were invited and received with the utmost courtesy. The attendance was large, and would have been even greater had it not been that Dr. and Mrs. Charles gave a *musicale* the same evening that took away many of the most distinguished English and American visitors. The entertainment was one of the most delightful of all the Congress week.

Tickets for Sale.—Special tickets of admission to the various entertainments were freely sold by the "Portiers" of the different hotels, and even by street pedlers, but were often difficult to be obtained by the members of the Congress for whom they were intended. Only a comparatively small number of members were invited to the garden party given by the king at the Quirinal, but it was generally asserted as a fact that tickets to this entertainment were sold in a quiet way for five and ten francs a piece. The messengers to whom the tickets had been delivered for distribution simply did not give them to those for whom they were intended, but sold them and pocketed the proceeds. Entrance cards for the illumination of the Forum, the reception at the Capitol, and the lunch at the Baths of Caracalla were to be had at any of the hotels for a dollar a piece, and late comers could get them for fifty cents.

OUR LONDON LETTER.

ROMAN ECHOES—CHELSEA HOSPITAL—COLLEGE OF PHYSICIANS—PORTRAIT OF LATE PRESIDENT—LONDON HOSPITAL—NEW WING—TEMPERANCE HOSPITAL—ADVERTISING NOSTRUMS—MEDICAL SOCIETY—STRANGULATION OF INTESTINES BY BANDS—CLINICAL SOCIETY—RESECTION OF THE BLADDER—HIP-JOINT ANKYLOSIS—BILIARY COLIC—RUPTURED BILE DUCT—ANEURISM BY ANASTOMOSIS—DEATH OF BROWN-SÉQUARD.

London, April 7, 1894.

This week the Congress at Rome has occupied most of the conversation among the stay-at-home physicians. A fair number of Englishmen have taken the opportunity of a trip to Italy, and the news that has reached us is of success and enthusiasm. But you will have your own direct cable news, and here I only allude to the impression in London.

The Royal College of Physicians, at the request of the Chelsea Hospital for Women has undertaken to nominate a representative to serve on a committee to investigate the charges made by the Medical Officer of Health. The college has also passed a resolution in favor of the proposed Gresham scheme. This was to be expected, as the scheme is likely to benefit this as well as the sister college. But the scheme has not yet commended itself to the medical schools and will encounter strenuous opposition from the university. The Fellows of the college have also decided to have a portrait of Sir Andrew Clarke, their late president, in fact have commissioned Mr. Lehmann to paint one. An offer of Mr. Watts to present a replica of a likeness he had taken during the life of the lamented president has been declined! Nevertheless the Fellows, who want the portrait and will hold it as their monopoly with the other property of the college, are not willing to pay for it, and are sending round a circular to other members asking them to contribute—yes, begging from those to whom they refuse all privileges in their corporation! Begging them to pay for a portrait when they might have had one for nothing. No doubt the excluded will hurry to the help of the pockets of the excluders!

Sir Andrew Clarke will have a worthy memorial in the projected new wing of the London Hospital—for it is now decided to carry out this proposal, and the Duke of

Cambridge has fixed May 3d for a public meeting to promote this object, and Mr. Gladstone has promised to speak on the occasion.

The London Temperance Hospital has been established more than twenty years and has a good record of work done. In 1893 there were 1,036 in-patients, with 73 deaths, a percentage of 7.04. The rate of mortality for the whole period has, however, been only 6.3 per cent., a figure which might well gratify the subscribers at the annual meeting, when there was much enthusiasm. The hospital receives all sorts of cases, both medical and surgical, without distinction, and many of them, as may be supposed, are most grave and unpromising. The supporters, therefore, claim very fairly that twenty years' work, 9,000, cases and a mortality of 6.3 is as good an average as other hospitals show, and a proof that alcohol is not a necessity in the treatment of the most serious diseases. There have been 144 cases of enteric fever in the hospital during its existence, with 25 deaths, of which 4 were admitted moribund, reducing the percentage to 14.5. This is not excessive, if we make full allowance for the condition of hospital cases. The figure is, in fact, often surpassed, although in exceptional circumstances it is not reached. Considering the distribution of 144 cases over more than twenty years, many disturbing circumstances may have been present, and the number is too small to draw conclusions from. Probably in future a much less average will be attained.

I hear that your American Medical Association is discussing the question of quackery in its journals' advertising columns. The officials who want to finger the quacks' cash should have got a few wrinkles from their British parent. When the editor was among you why did you not ask the secret of beginning with special sherries and so on, and advancing to any nostrum, as some American manufacturers are pretty well aware?

On Monday, at the Medical Society of London, a case was related of acute intestinal obstruction due to strangulation by a band, and for which abdominal section was successful on two occasions, viz.: December, 1892, and September, 1893. On the last occasion Mr. Hutchinson, Jr., operated and found the constricting band closely connected with the adhesions of the old scar, so he brought the peritoneum together over the raw surface by a continuous suture, in order to lessen the chance of new adhesions. Another case was related by Dr. Pasteur and Mr. Bland Sutton, in which a constricting band was successfully divided. Mr. Sutton advocated incisions through the linea alba and objected to the triple row of sutures, as did also Mr. Lockwood and others.

The last meeting of the Clinical Society was devoted to surgery, and the programme was rather full, perhaps on account of the interruption of the meeting at Easter. A case of resection of the bladder for recurrent epithelioma was related by Mr. H. Fenwick. The first operation was perineal, and the growth proved to be epithelial. It recurred in a year, and then was removed by the suprapubic method, and the base seared with Paquelin cautery. In seven months it recurred, and therefore the tumor and the left lateral wall and base of the bladder which it occupied were completely resected. The patient has now, nine months after, full control of the bladder.

Some discussion next occurred on two cases of rectangular ankylosis of the hip, related by Mr. Heath. One was treated by Adams's operation, the other by Sayres's.

Biliary colic was the next subject, and Mr. A. Lane reported a case relieved by the removal of calculi. Mr. Battle related a case of traumatic rupture of the common bile duct in a boy of six, who was run over by a cab. The duct at the post-mortem was found torn completely through—a rare if not unique occurrence. These cases illustrate the innocuousness of healthy bile in the peritoneum, though in disease we may suppose that some changes have occurred.

Mr. Turner read notes of a case of aneurism by anastomosis in the temporal region, where it so often occurs. Some vessels had been ligatured, but without much benefit, and the child's parents refused further treatment. Otherwise various procedures were suggested, including ligature of the carotid.

The death of Brown-Séquard you will have heard of as soon as we did, for he was American enough to be claimed by you apart from his great reputation. He was also a resident here in London, and the National Hospital for Epilepsy and Paralysis here was established for him. A wonderful personality was his, and he made a practice in London, in Paris, in New York. Such a career would be in itself most remarkable, and is, in fact, I think, without parallel and likely to remain so. But when we add to this his physiological work we may well be lost in wonder.

LETTER FROM ROME.

(From our Special Correspondent.)

CONCERT AND BICYCLE RACES—MISLEADING ANNOUNCEMENTS IN THE OFFICIAL JOURNAL—BLUNDERS OF THE MANAGEMENT—ILLUMINATION OF THE RUINS—RECEPTION AT THE CAPITOL—CLOSING SESSION—LUNCH AT THE BATHS OF CARACALLA—CLOSING FESTIVITIES—GENERAL VERDICT OF CONGRESS.

Rome, April 6, 1894.

Sunday was a day of rest from scientific labors, and given up to excursions and entertainments of various kinds. Many of the members went to Tivoli and Frascati, others attended private meetings at the houses of Rome's most prominent physicians; numbers spent the day in visiting the ancient monuments, galleries, and churches; and others again rested or went to the concert or the velocipede races. A concert was given by the municipality in honor of the Congress in the Costanzi Theatre. It was announced that this would take place at three o'clock, and many went there at that hour only to find that it was over. The time appointed was one o'clock, and the announcement of a time two hours later was simply in keeping with the stupidity and inaccuracy of every official publication of this Congress. The concert was really an excellent performance, but it was given to a nearly empty house in consequence of this inexcusable blunder. At three o'clock there was a bicycle race at the Tor di Quinto, a race-track some two miles from the city. It was a well organized and creditable affair, the time made by some of the winners being phenomenal. The king was present and manifested great interest in the contests. In spite of the difficulties presented by the steep hills of Rome, bicycling is steadily growing in favor here, and wheelers are to be seen everywhere. The only wonder is that, with the reckless driving of the Roman cabbies, they are not run over. Pedestrians are in constant danger, for only the more important streets have sidewalks, and even these are so narrow that foot-passengers are forced to take to the roadway.

On Monday morning the members from the United States and Canada held a second meeting, and listened to the usual complaints of neglect and discourtesy on the part of the Congress officials. A delegate present said that he had been sent by his government to prepare a report of the meeting. He was unacquainted with Italian, but had been assured by the managers of the Congress that there would be no difficulty on this score, and that he would be provided with every facility for acquiring information. He had come without secretaries or interpreters, on the strength of this representation, and found himself entirely at sea. He had met hardly anybody officially connected with the meeting who could speak intelligible English, and those knew nothing of what had been or would be done. It would have been little better if he had brought an interpreter, for the natives themselves seemed to be as much in the dark as the foreigners.

The official journal of this day contained an announcement that there would be a general session at the Eldorado Amphitheatre, as usual, in the afternoon, at which

Dr. Danilewsky, of St. Petersburg, would read his address on "The Fundamental Substance of Protoplasm and its Modifications by Life." A large number of the members went to the place at the appointed time, only to find a notice posted up to the effect that there would be no meeting this day. Being near the Palace of Fine Arts they thought they would employ the time, otherwise wasted, in a visit to the Medico-hygienic Exhibition, but on presenting their membership cards were refused admittance. It was learned afterward that several packages of blank cards had been abstracted from the office of the Congress, and the officials in their wisdom had decided to cancel all the tickets previously issued and exchange them for new tickets of another color. No notice of this change was given to the members, however, and the only way they had to learn of it was by being turned away by a surly policeman from places which they had been told they had a right to enter. The following day when they applied for new tickets at the office of the Congress, they were refused the new tickets and told the old ones were valid, notwithstanding reports to the contrary, only the Italian members were obliged to get tickets of another color. So they kept the old ones, which were sometimes recognized and sometimes were not, according to the will of the policeman stationed at the door.

The instances of this mismanagement on the part of the officials of the Congress were innumerable, and a mere catalogue of them would fill pages. If it had been the intention of the managers to inconvenience their guests to the utmost possible extent they could not have succeeded better than they did by their stupidity and blundering.

The illumination of the ruins was very fine, almost as good as Payne's fireworks at Coney Island. There was first an illumination of the Forum, Palatine Hill, and Colosseum by Bengal lights, then a lighting up of the neighboring hills and dome of St. Peter's by searchlights, and finally a show of rockets and Roman candles. The air was quite chilly, and many paid for their fun by a pretty severe coryza the following day.

Tuesday morning was given up to section work at the Polyclinic, several Americans getting an opportunity, which had previously been denied them, of presenting their papers. In the afternoon a general session was held at the Eldorado. Dr. Bizzozero, of Turin, read an address on growth and regeneration, and this was followed by the address of Danilewsky, of St. Petersburg, which had been announced for the day before.

In the evening a reception was given by the Municipality of Rome on the Campidoglio or Capitoline Hill. The buildings surrounding the square of the Campidoglio were very tastefully illuminated, and the square itself was a mass of flowers, ferns, and palms. The throng that filled the Capitoline Museum and Palace of the Conservators was immense, and in certain parts the crush was almost perilous. The little room in which the Capitoline Venus is lodged was illuminated with a pale red light, and the wonderful figure stood out in all its loveliness—one of man's most marvellous productions. Among those present perhaps the most notable was Virchow, whose progress through the halls was like that of royalty itself, the crowd that surrounded him being almost as great as that looking at the Venus, although the attraction in the two cases was of a very different kind.

On Wednesday afternoon addresses were delivered at the general session by Jacobi, of New York, Kocher, of Berne, and Stokvis, of Amsterdam. That of Kocher was upon gunshot wounds, and was of a nature more suited to the Section on Military Surgery than to a general session of the Congress. It was illustrated with numerous plates, diagrams, and bones, which made a great show on the stage but were referred to only in small part by the speaker. The lecture was in German, delivered with a strongly marked Swiss accent. Dr. Jacobi followed with his address, entitled "Non Nocere." The Latin title was transformed into the Italian "Non Nuocere" on the official programme, and the result was a large attendance of Italians, who expected to hear an address in their own tongue. They were disappointed, but those who understood English were not, for the address was one of the most practical and sensible of the entire number. It contained no new truths, except possibly that relating to the results of craniotomy in idiocy, but it enforced many old ones that are in danger of being ignored. The speaker had regard for the lateness of the hour and to the fact that there was yet an address to come, and spoke very briefly but to the point. With the exception of Laache, Dr. Jacobi was the only speaker who stopped while his auditors were still desirous of hearing more. After this came a long but well-delivered and interesting discourse in French by Dr. Stokvis, of Amsterdam, on "Chemistry in its Relation to Pharmaco therapeutics and Materia Medica." The speaker, while recognizing to the full the services rendered to this branch of medicine by chemistry, was not sparing in his denunciation of the fashion of running after the new synthetic remedies, the "antis" of all sorts, which appear with such monotonous regularity from German laboratories. He did not say that all these were useless, but urged the necessity of proving them most carefully before adopting them in therapeutics.

In the evening ten of the nineteen sections met in different restaurants and hotels for the usual dinners. The ordinary toasts were drank, the ordinary congratulations exchanged, and the members dispersed at a late hour.

On Thurday morning the closing session was held at the Eldorado, the president being in the chair. He made a short address referring to the work accomplished during the meeting, thanking the foreign and Italian delegates for their part in contributing to the success of the Congress, and expressing the hope that all would return to their homes carrying with them pleasant and lasting memories of their visit to Rome. Then the chairmen of the foreign delegations spoke briefly, thanking the profession and government of Italy and the citizens of Rome for the part they had severally taken in contributing to the comfort and entertainment of their guests. The question of the place of meeting of the Twelfth Congress then came up, and after a short discussion Russia was chosen almost unanimously. The czar had consented to allow the meeting to be held in his dominions, but had not expressed his will as to the city, whether it should be St. Petersburg or Moscow. The selection was accordingly left open pending his decision. Dr. Danilewsky, in behalf of his government and of the Russian physicians, thanked the Congress for selecting Russia, and was sure that all who came to the next meeting would have no reason to regret the choice they had made. The president then declared the Congress closed.

At noon a lunch was given to the members in the ruins of the Thermæ of Caracalla. Several thousands were present, but so vast is the structure that there was no crowding anywhere except around the lunch-tables. A pretty feature of the entertainment was the setting free of a thousand pigeons by the Carrier Pigeon Society of Rome. The birds rose almost together and hovered for a moment over the ruins, as if to get their bearings. But the crows, who have for ages made the old walls their resting-place, resented this intrusion of their domains, and attacked the strangers, dispersing them in all directions. The column was soon reformed, however, a little distance away from the ruins, and then the pigeons started in a long line toward the north.

In the afternoon a battle of flowers took place on the Corso. The crowd of spectators lining the street was immense, but the combatants were chiefly foreigners, the Romans seeming to have lost their taste for this pretty festival. In the evening there was a short but very beautiful allegorical lantern procession, accompanied by the *ritirata dei moccoletti*, a game in which each person carries a lighted taper and tries to extinguish his neighbor's while keeping his own alight.

With this ended the festivities of the Congress, and the exodus to Naples began.

The general verdict concerning the Congress was that it might have been much better. The scientific work was of comparatively slight importance, and the want of direction was everywhere apparent, the misleading notices in the official journal contributing in no small measure to the general confusion.

New Instruments.

A NEW OPHTHALMOSCOPE.

By PETER A. CALLAN, M.D.,

NEW YORK.

The accompanying cut illustrates a modification of the Loring ophthalmoscope devised by Dr. A. W. O. Roth,

Fig. 1.

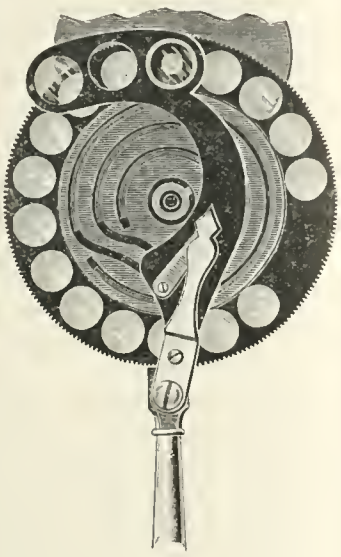

Fig. 2.

of Berlin. By its means the surgeon can make use of the entire series of lenses without removing the instrument and adjusting the quadrant. The mechanism is ingenious, consisting of a concentrically grooved disk in which a guiding-pin rests. The pin perforates the supporting shank of the quadrant, and runs in the grooved surface of the disk, between the pivot and the lenses. On turning the disk, the quadrant is automatically brought into play, through the connecting guiding-pin.

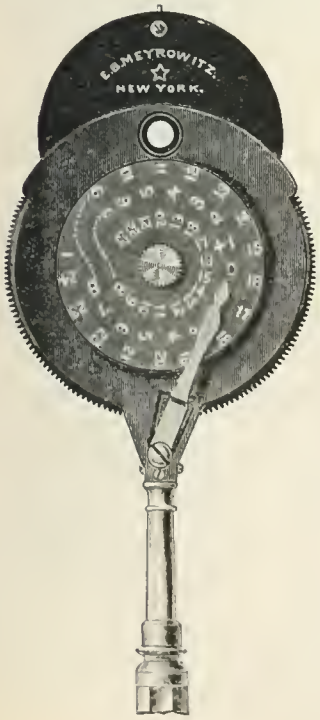

Fig. 3.

The ophthalmoscope of Dr. Roth contains 15 large lenses: 7 convex, ranging from + 1. D to + 7. D, and 8 concave, from — 1. D to — 8. D. The quadrant contains 1 + 16 and 1 — 16 lens, which in combination with the other lenses furnish the complete series up to + 23. D. — 24. D. or a total of 47.

In addition to the lenses contained in the disk and quadrant, a + 0.50 D lens is mounted in a slide attached to the front of the instrument, directly behind the tilting mirror, in such a manner that it can instantly be brought into combination with any of the lenses contained in the series by an easy and natural movement of the index-finger, thus giving a regular interval of 0.50 D throughout the entire series from + 0.50 D to + 23.50 D, and from — 0.50 D to — 24 50 D, making in all 95 distinct combinations.

Fig. 1 shows the back of the ophthalmoscope, with the index finger, which moves automatically with the quadrant and indicates the lens *in situ* on the dial. Fig. 2 shows the interior mechanism of the instrument; and Fig. 3 gives a front view, with the slide holding the + 0.50 D lens in dotted lines. It also shows a small driving-wheel below the disk, which is placed on the instrument if desired.

E. B. Meyrowitz manufactures this modification of the Loring ophthalmoscope.

35 West Thirty-eighth Street.

UTERINE DILATOR WITH NEW SELF-ACTING LOCK.

By AUGUSTIN H. GOELET, M.D.,

NEW YORK.

This modification of the Sims uterine dilator is presented for the purpose of exhibiting a new instrument lock, designed by the writer, which is much more simple and more easily adjusted than those now in use. It is applicable to all two-bladed instruments, such as forceps, scissors, etc., when it is desirable to separate the blades to render them thoroughly aseptic.

The arrangement is such that the blades are unlocked and separated easily, when their relative position is that in which the instrument is never used. For instance, in the instrument shown, when the handles are closely approximated the blades fly apart. Scissors and forceps are unlocked when the handles are widely separated.

The details of construction of this lock are nicely shown in the cut. At *a* the instrument is shown locked. At *a'* the lock is open, showing the male and female portions, which fit into each other. A slot in the female blade permits the pivot with its head, which is flattened on both sides, to come together when the blades are in proper position, and the slightest turn locks them securely.

The original instrument is improved by giving it a less acute curve, by curving the handle and attaching a ratchet for holding the dilatation secured, and relieving the hand when it becomes tired. This ratchet is so adjusted that by a very slight pressure of the little finger it can be quickly released if the instrument slips backward and threatens laceration of the cervix, an accident which is not infrequent. It is attached to the left-hand blade by a novel device shown at *b*, which permits it to be detached readily.

An Improved Intra-uterine Double-current Irrigator. Modification of the Fritsch-Bozeman Double-current Catheter

The writer believes that the instrument presented is a decided improvement. The main features of the modification are that the instrument is two inches longer than the original, so that it can be used to better advantage in deeper cavities, and the inside tube, which conducts the inflow, is extended to the extremity of the outer tube, conducting the outflow.

The advantage of this improvement is that the injected fluid escapes from the point of the instrument instead of at the sides, and in this manner comes more satisfactorily in contact with the whole cavity. This is a greater advantage when the canal is narrow or obstructed at any portion by a tumor projecting from the uterine wall, making the point of the instrument fit snugly so that no fluid will pass it without some force.

In a case of this kind, with the original instrument it would only be possible to wash that portion of the canal included by the fenestra of the cannula, as the point of the instrument would block the canal and prevent the entrance of the solution to that portion of the cavity beyond. With the modified instrument that portion of the cavity beyond the point of the instrument can be satisfactorily flushed. The fenestræ in the cannula have been extended up nearer the point, so that a return flow will be certain. In place of the usual fenestra at the outer end of the cannula, an attachment is added for affixing a rubber tube to carry off the outflow to a basin or bucket below, which I regard as an additional advantage.

The advantages of this instrument are more particularly manifest in the fibroid uterus, where the calibre of the canal is so often contracted at a certain point and the cavity beyond is dilated. It would be better still if the cannula was made a little longer, and I have directed the makers, Messrs. George Tiemann & Co., to make another size having a cannula ten inches long.

Medical Items.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 28, 1894.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	6	1
Scarlet fever	146	10
Cerebro-spinal meningitis	0	4
Measles	294	15
Diphtheria	197	46
Small-pox	17	4
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

The Surgical Instruments of Antiquity.—Dr. Deneffe, of Antwerp, after twelve years of labor in collecting material has published a most interesting treatise on ancient surgery. He has obtained between six and seven hundred specimens, including copies. Among them, says a writer in *The Medical Magazine*, are uterine and anal specula, knives, lancets, forceps or volsellæ, scissors, spatulæ, all kinds of sounds, scarificators, rugines or raspatories, probes, cauteries, caustic-holders, cannulæ, needles, curettes, hooks for the extraction of the fœtus in difficult labors, saws, ointment tubes, a needle for couching (cataract), tooth forceps, urethral sounds (male and female), besides many others we have not space to mention.

With the exception of the trivalve and quadrivalve uterine specula, which can compare with the finest modern work, the instruments of those days were simple in the extreme. To carry out their ideas the early surgeons had to rely on intelligent locksmiths, who, it must be said, faithfully followed instructions, and in some cases produced instruments of exquisite finish. Usually they served a double purpose, one end of the instrument being used as a curette, the other end as a spatula, and so on. Sometimes knives, curettes, or elevators of different sizes formed the two extremities. The various kinds of forceps were generally only used for one purpose; some, however, are supplied with an aural curette, a probe, etc., the object being to simplify and to make the surgeon's case more portable.

Most of the instruments of antiquity are bronze, which chemical analysis has shown to be composed of copper and tin, sometimes lead, and more rarely, zinc being added; in exceptional cases gold and silver have also been found. Some of them are made entirely of copper, as the ancients knew how to temper this metal by heating it to redness and then rapidly plunging it into cold water. Silver instruments are rare, but silver was used in some instances to damascene those made of bronze. Fragments only of iron instruments have come down to us. According to Lepsius, the Egyptians employed iron 4,000, and the Greeks 1,450 years before Christ. Dr. Deneffe points out, too, that Homer frequently refers to this metal. There are some specimens of knives with iron blades and bronze handles; also an iron hook in a bronze handle for extracting the fœtus from the womb. As iron is perishable it cannot be stated positively to what extent it was used.

According to the author, the instruments found at Herculaneum and Pompeii (first century) lack the finish of those discovered in France, Belgium, and near the Rhine, and which date from the second and third centuries. He does not think, however, that the latter were made in the countries where they were found. It is probable they were imported into these Roman colonies by surgeons, who supplied themselves in Italy before starting.

A remarkable thing about all these instruments is that they are made entirely of metal; wood, ivory, or shell never being used.

The Drink Question in America.—A committee of the "Sociological Group" has been formed in this country for the purpose of investigating the "liquor problem" in its physiological, ethical, and legislative aspects. The committee includes such representative divines as Cardinal Gibbons, Archbishop Ireland, Rabbi Gottheil, Bishop E. G. Andrews, besides physicians and men of science like Dr. J. S. Billings, Professor Bowditch, of Harvard; Professors Furnam and Chittenden, of Yale; Dr. Weir-Mitchell; and public men like President Eliot, President D. C. Gilman, Mr. Cornelius Vanderbilt, and others. Physiological experiments on a large scale are proposed, and the investigation is to be made as complete as possible.

DIGESTIVE PROTEOLYSIS.

THE CARTWRIGHT LECTURES FOR 1894.

BY R. H. CHITTENDEN, PH.D.,

PROFESSOR OF PHYSIOLOGICAL CHEMISTRY IN YALE UNIVERSITY.

(Continued from page 550.)

LECTURE III.

PART II.—ABSORPTION OF THE MAIN PRODUCTS OF PROTEOLYSIS.

IN ordinary proteolytic action, both in the stomach and intestine, it is very apparent that the primary products of proteolysis, the proteoses and peptones, are the chief products formed, and that under normal circumstances the greater portion of the proteid food finds its way from the alimentary canal into the blood, after transformation into one or more of these two classes of products. At the same time, it must be borne in mind that even the acid-albumin formed by pepsin hydrochloric acid may be absorbed without undergoing further change. The view once held, that the rate of absorption from the alimentary tract stands in close relation to the diffusibility of the products formed, and that non diffusible substances are incapable of absorption, is no longer tenable. Absorption from the intestine is to be considered rather as a process involving the vital activity of the epithelial cells of the intestinal mucous membrane, where chemical affinities and other like factors play an important part in determining the rate and order of transferrence through the intestinal walls into the blood and lymph. Thus, we have abundant evidence that native proteids which have not undergone proteolysis may be absorbed from the intestine, at least to a certain extent, provided they have been dissolved; *i.e.*, converted into acid-albumin, or alkali-albuminate, by the gastric or pancreatic juice. We have a practical demonstration of this possibility in the early experiments of Voit and Bauer,[1] as well as in many later ones that need not be mentioned here. Further, the recent experiments of Huber [2] have given us quantitative data on the rate of absorption of fluid egg-albumin when introduced into the large intestine in the form of a clyster, showing that even fairly large amounts of a natural proteid may be absorbed without undergoing proteolysis if mixed with a neutral salt, like sodium chloride. To be sure, the rate of absorption is greatly increased when the albumin has been peptonized, but still absorption of the native proteid is possible without the agency of proteolytic enzymes. When, however, large amounts of egg-albumin are introduced into the intestine, albuminuria may result, as you very well know.

Moreover, it is well known that the proteids of muscle tissue, in the form of syntonin, may be absorbed from the large intestine without undergoing further hydration. When introduced into the rectum of a hungry dog, the excretion of urea may be at once increased and the animal brought into a condition of nitrogeneous equilibrium; absorption taking place from a portion of the large intestine, where proteolysis is never known to occur.[3]

[3] Eichhorst: Ueber die Resorption der Albuminate im Dickdarm, Pflüger's Archiv f. Physiol., Band 4, p. 570.

Again Neumeister[1] has shown that the direct introduction of syntonin, alkali albuminate, crystalline phytovitellin, as well as pure serum-albumin, into the blood of the jugular vein is not attended with the appearance of albumin in the urine. On the contrary, the proteid matter so introduced appears to be assimilated and utilized for the needs of the organism. Evidently, then, these substances are not to be considered as foreign bodies, for if so the kidneys would undoubtedly make some effort to remove them from the circulation. It is to be noted, however, that all native proteids are not assimilated in this manner, as casein,[2] gelatin,[3] and especially egg-albumin. Thus, J. C. Lehman,[4] working under Kühne's direction, observed that the injection of a carefully filtered solution of egg-albumin into the veins of a dog was always accompanied by albuminuria, while similar injections of Lieberkühn's sodium albuminate, or of syntonin from frog's muscle failed to show any such result.

While these observations tend to show that some native proteids may be absorbed from the alimentary tract without previously undergoing proteolysis, it is not to be understood that any considerable quantity is so absorbed under normal circumstances. Doubtless, when small amounts of proteid food are taken, its denaturalization by the primary action of the gastric or pancreatic juice, viz., its conversion into syntonin or alkali-albuminate, may be sufficient to insure its partial absorption, but digestive proteolysis is unquestionably a necessary preliminary to any general absorption, and there can be no manner of doubt that the greater portion of the proteid food is absorbed as proteoses and peptone. Peptones, as we have seen, are possessed of a higher endosmotic equivalent than the proteoses, but we need to keep continually in mind the possibility that the selective power of the epithelial cells of the intestinal mucosa may lead to as rapid transferrence of the proteoses as of the more diffusible peptones. It is not to be understood by this, however, that diffusibility is of no consequence in determining the rate of absorption. Surely, everything else being equal, the more diffusible the substance the more rapid will be its passage from the intestine into the blood-current. The more the process of absorption is studied, however, the more clearly do we see its dependence upon the functional power of the living epithelial cells, a fact which plainly emphasizes the physiological nature of the process.

Further, as already stated, absorption of proteid foodstuffs, or their products, from the alimentary tract, is, under ordinary circumstances at least, limited to the intestine; from the stomach there is comparatively little absorbed, and if necessary we might advance this fact as an important argument against the theory of general absorption of proteids in the form of acid-albumin. Even such indifferent fluids as water, or physiological salt solution, are absorbed with extreme slowness from the stomach;[5] this organ showing very little ability to take up water even when the blood vessels are dilated, as after the ingestion of food.

This brings us to a very important point in connection with the utilization by the system of the ordinary products

of proteolysis. The latter, as we have seen, are mainly proteoses and peptones, and yet all the evidence points clearly to the fact that these substances are never present, at least in any quantity, in the blood or lymph, even when digestive proteolysis is at its height. Further, the very nature of the proteoses and peptones, their marked physiological action when they are introduced directly into the circulating blood, their rapid excretion either as proteoses or peptones by the kidneys when so introduced,[1] all indicate that they are foreign substances, totally out of their natural environment when introduced into the blood-current. And yet we very well know that proteoses especially are possessed of high nutritive qualities; they are abundantly able to support animal life. Thus, Politzer[2] found by feeding experiments with heteroalbumose, dysalbumose, and protoalbumose that these bodies taken into the stomach have the same nutritive value as meat. Various feeding experiments with proteoses from different sources, carried out in my laboratory on young dogs, have shown conclusively that for short periods of time, at least, these hydrolytic cleavage products are fully as capable of sustaining the nitrogeneous equilibrium of the body as the proteids from which they are derived. In fact, the results obtained favor the view that the proteoses, weight for weight, possess a higher nutritive value than fresh beef.[3] It may be questionable, however, whether such a result would follow in experiments conducted over longer periods of time, but of this we may be certain that the proteoses formed in the alimentary tract can be absorbed and utilized by the system without their exerting any toxic action whatever.

Consequently, we are forced to the conclusion that these primary products of proteolysis, so important in the nutrition of the animal body, must undergo some change during the process of absorption, by which they are converted into new bodies, less toxic in their nature, and better adapted for the direct nutritional needs of the organism. The same statement applies likewise to peptones.

The fact that peptones are not discoverable in the blood and lymph, even during or after active digestion, was practically ascertained years ago by such well-known workers as Maly, Adamkiewicz, and others. The natural supposition following this observation was that the products of proteolysis underwent some change in the hepatic cells; but this view was soon shown to be untenable by examination of the portal blood, which was found to be as free from peptone as the blood of the hepatic vein. Neumeister,[4] using the more modern methods of work and with the wider knowledge gained during these latter years, has shown conclusively that proteoses and peptones are never present in the blood, even when these substances are contained in the intestine in fairly large amounts. I can corroborate these statements from the results of my own experiments in this direction. Thus, I have taken a dog in full digestion, fed with an abundance of meat, and collecting the blood from the carotid artery have made a careful examination for peptone, by the following method: The blood was allowed to flow directly into a dilute solution of ammonium sulphate, sufficiently strong to prevent coagulation, and then shaken with ether to rupture the red blood-corpuscles. The solution, freed from ether, was next saturated with crystals of ammonium sulphate, by which the proteid matter was completely precipitated. The clear filtrate was then concentrated somewhat, the excess of the ammonium salt removed by filtration, and the filtrate carefully tested for peptone by addition of a large volume of a saturated solution of potassium hydroxide and a few drops of a dilute solution of cupric sulphate. The test was wholly negative, although the intestine of the animal showed the presence of both peptone and proteoses. This result, as I have said, is simply confirmatory of work done by others in this direction, notably Neumeister, and illustrates the statement that peptones are not to be found in the circulating blood, even after a full proteid diet. In this connection it is to be remembered that we have abundant proof of the rapid disappearance of both proteoses and peptones[1] from the intestine, either by absorption or otherwise. They certainly disappear, and, as we have seen, are not to be found in the blood. Further, Neumeister has confirmed the original observation of Schmidt-Mülheim,[2] that both chyle and lymph are practically free from proteoses and peptone, thus again forcing us to the conclusion that the primary products of proteolysis must undergo change prior to their passage into the blood or lymph.

Many observations lend favor to the view that a transformation of some kind takes place in the intestine itself, not indeed in the lumen of the tube but somewhere in the walls, through which the peptones must pass before reaching the blood. Thus, peptones placed in contact with pieces of the isolated, though still living, intestine, after a time completely disappear from view,[3] so completely that no reaction can be obtained even by the most delicate of tests. In support of this statement I may cite the results of several of my own experiments which certainly furnish evidence that true peptones undergo profound alteration by simple contact with the living mucous membrane of the small intestine. The method employed was similar to that made use of some years ago in a study of the influence of peptone on the post mortem formation of sugar in the liver.[4] A large, well nourished rabbit was killed by severing the carotid artery and the blood collected and defibrinated. Of this, 50 c.c. were mixed with an equal volume of 0.5 per cent. salt solution containing 1.25 gramme of pure amphopeptone, prepared from egg albumin, the mixture obviously containing 1.25 per cent. of peptone. The fluid was transferred to a large, roomy flask, provided with a stopper having two holes, in one of which was fitted a long glass tube reaching below the fluid. The flask, with its contents, was then placed in a suitable water bath at a temperature of 40° C.

The small intestine of the rabbit was carefully separated from the mesentery and from the pancreatic gland, and the upper portion cut open and quickly washed free from any contained matter or adherent secretions, by repeated immersion in 0.5 per cent. salt solution warmed at 40° C. This was repeated until the tissue was quite free from all impurities, after which it was cut into small pieces and immersed for a moment in a 0.5 per cent. solution of sodium chloride containing 1.25 per cent. of peptone. The tissue was then carefully collected on coarse muslin, allowed to drain, and then quickly transferred to the flask containing the warm blood and peptone. This mixture was kept at 40° C. for two hours, a slow current of air being bubbled through the fluid during the entire period. At the expiration of this time the fluid was separated from the pieces of tissue by filtration through muslin, and then saturated with ammonium sulphate after the usual method for the separation of albumoses, etc. On now testing a portion of the clear filtrate for peptone by the biuret test, not a trace of a reaction could be obtained. The entire amount of proteid matter present was precipitated by the ammonium salt, thus showing that the peptone originally added had been completely transformed into something precipitable by saturation of the fluid with ammonium sulphate. That

this tranformation of the peptone was accomplished mainly through the action of the intestine, was shown by a parallel experiment, in which all of the above conditions were duplicated, omitting only the pieces of intestine. Here, however, on testing the filtrate from the ammonium sulphate precipitate, a strong biuret reaction was obtained, thus proving the presence of at least some unaltered peptone.

This experiment is almost a counterpart of one reported by Neumeister, and like his, testifies to the probability that the peptones formed in the alimentary tract as a result of proteolysis undergo retrogression through the agency of the epithelial cells of the intestinal walls during their absorption. I have tried similar experiments with deuteroproteose, notably with deuterocaseose, and have obtained corresponding results. The same method may be employed as that already outlined, although of course the deuterocaseose is in great part precipitated by saturation with ammonium sulphate. Still, this form of deuteroproteose, β deuterocaseose, as I have elsewhere noted, is very slowly precipitated by the ammonium salt. Consequently, it is an easy matter to demonstrate that this proteose, on treatment with the intestinal mucosa in the presence of blood at the body temperature, is transformed into something completely and readily precipitable by ammonium sulphate; the filtrate from the latter failing to show any biuret reaction, although the corresponding control experiment without the intestine gives a bright violet color with cupric sulphate and potassium hydroxide.

Hence we are certainly justified in saying that both peptones and proteoses undergo some retrogression when in contact with the walls of the intestine. Moreover, there is some evidence that the proteoses, before undergoing such a transformation, are first converted into peptone by the action of the intestinal walls, a statement which will apparently apply to both the primary and secondary proteoses. This primary action of the intestinal walls is not considered as due to any adherent trypsin, or to possible traces of succus entericus, but rather as a part of the action of the living epithelial cells, or perhaps as connected with the possible presence of lower organisms not removable from the intestinal wall by ordinary washing.

The transformation of peptones by the substance of the intestine is apparently common to the intestinal tract of many animals, and perhaps to all, and indeed can also be accomplished by the liver.[1] This latter fact is of some importance, since it adds weight to the supposition that this peculiar action of the intestine cannot be due to the possible presence of trypsin; a view which is strengthened by the fact that a glycerin extract of the intestine has no action on amphopeptone. Certainly, the latter shows no diminution in the strength of the biuret reaction after long contact at body temperature with such an extract. Further, it has been shown that antipeptone, which is not affected by the pancreatic enzyme, suffers the same change as amphopeptone by contact with the intestine. Far more probable is it that retrogression or transformation of peptone by the substance of the intestine, is due to the vital activity of some or all of the epithelial cells of the intestinal mucosa; a characteristic possibly shared by some or all of the hepatic cells of the liver. The kidney cells certainly do not possess this power, but we can see a special fitness in the liver cells being endowed with the ability to quickly break down, or transform, any peptone or proteose that might by chance escape unaltered from the intestinal tract. Shore,[2] however, inclines to the view that the hepatic cells do not possess this power to any great extent, in opposition to the older views of Plósz and Gyergai,[3] as well as of Seegen [4] and of Neumeister.

With reference to the action of the stomach mucosa on proteoses, it has been shown [1] that when relatively large amounts (5 grammes) are introduced into the stomach of a rabbit, the pylorus being ligatured, both proteoses and peptones may appear in the urine, thus indicating that while they may be absorbed to some extent under the above conditions, the proteoses are not readily transformed into native proteids without exposure to the intestine. Smaller amounts, however (2 grammes) may, under the above conditions, be completely transformed; at least Hildebrandt claims this to be the case, mainly on the ground that after the introduction of albumoses into the stomach, the pylorus being ligatured, no trace of them could be found in the urine. The same observer also claims that blood serum, in the case of dogs, is able to transform albumoses into ordinary serum globulin. Certainly, after intra-venous injection, proteoses disappear from the blood, but, as we shall see later on, a certain amount, at least, may be transferred to the lymph. It is also claimed that when albumoses are injected subcutaneously neither albumoses nor peptones are to be detected in the urine. This, however, seems hardly probable in the light of what has been said, and especially in view of the fact that Neumeister's experiments tend to show that even 0.1 gramme of albumoses introduced subcutaneously may give rise to temporary albuminuria.

Assuming for the moment that the chief products of proteolysis, *i.e.*, the proteoses and peptones, are, during the act of absorption, transformed through the vital processes of the epithelial cells of the intestine into serum-albumin or globulin and absorbed as such into the blood, we may well consider whether such transformation, *i.e.*, a retrogression into a native proteid again, is inconsistent, or out of harmony, with the general character of the changes known to occur in the body. In attempting to answer this question we need not look far to find a perfectly analogous case. Thus, in the digestion of starchy foods by the amylolytic ferments of both the saliva and the pancreatic juice, the carbohydrate material undergoes hydration with formation of dextrins and maltose, the latter, at least, being quickly absorbed into the circulating blood. But large quantities of sugar in the blood are certainly inimical to the wellbeing of the organism, and we find in the liver a tendency for the sugar to undergo a transformation, *i e.*, a retrogression into glycogen, either through simple dehydration or otherwise. Further, with reference to the possible conversion of proteoses into peptone by the substance of the intestine, we have a perfectly analogous case in the behavior of the intestinal mucous membrane toward maltose, the final product of amylolytic action. Thus, according to the recent work of M. C. Tebb,[2] the mucous membrane of the intestine has the power of transforming maltose into dextrose; simple warming at 40° C. of a solution of maltose in 0.5 per cent. sodium carbonate with a few grammes of the dried mucous membrane from the intestine, being sufficient to insure a marked conversion of maltose into the higher reducing sugar, dextrose. This observation, I can confirm from experiments just completed in my own laboratory. This action is presumably due to a ferment, which, according to Tebb, is widely distributed throughout the body, being present not only in the intestine, but also in the liver, kidney, spleen, striated muscle tissue, and, indeed, in the blood-serum; so that it would appear that nearly all the tissues of the body are endowed with the power of transforming maltose into dextrose. These statements being correct, it would seem that, while the amylolytic ferments of the several digestive juices transform, by hydrolytic action, starchy foods into maltose, the latter is exposed during its passage through the intestinal wall, as well as in the blood itself, to another ferment which carries the hydration still further, with formation of dextrose; and yet the latter product is destined, in part at least, to undergo retrogression into a

starch like body, *i.e.*, glycogen, before it is completely utilized by the system. Thus, the analogy between these carbohydrate bodies and the products of proteolysis is complete, and we may well accept the statements already made regarding the ultimate fate of the proteoses and peptones formed during proteolysis, as in no way inconsistent with the general tenor of events going on in the body.

While we are inclined to believe that the chemical changes attending the absorption of proteoses and peptones occur mainly in the epithelial cells of the intestinal mucosa, and that there is a direct transferrence of the alteration-products to the blood, there are still other views that cannot be wholly ignored. Thus, the view originally advanced by Hofmeister,[1] in which special stress is laid upon the functional activity of the leucocytes of the adenoid tissue surrounding the intestine, demands some consideration. The theory supposes that these cells not only have the power of taking up peptones, but also of assimilating and transforming them into the cell protoplasm. This view being correct, it is plain that the so-absorbed proteid must pass into the circulating blood through the thoracic duct, and Hofmeister further considers it probable that the lymph cells of the mesenteric glands can transform any absorbed peptone that may escape the leucocytes of the adenoid tissue.

In apparent harmony with this view is the fact that the leucocytes in the adenoid tissue of the intestine are greatly increased in number during digestion.[2] Furthermore, it is a well-authenticated fact that the proteoses or peptones found in pus are contained in the pus cells themselves, and not in the fluid in which the corpuscles float.[3] In support of the first statement, Pohl,[4] in his recent study of the absorption and assimilation of foodstuffs, has emphasized the marked increase in the number of the white blood corpuscles in the circulating blood after the ingestion of proteid foods, especially such as meat, Witte's peptone, and gelatin-peptone. It is to be noted further that the increase is most marked at about the third hour after the taking of food, viz., at a time when digestive proteolysis would naturally be at its height. Moreover, the maximal increase, according to Pohl's data, is astounding, amounting as it does in many cases to a hundred per cent. Thus, in one instance, in the case of a dog, the number of white blood-corpuscles per cubic millimetre of blood was 8,689; yet two hours after the feeding of 100 grammes of meat the number increased to 17,296 per cubic millimetre, followed six hours after by a return to the original figure.

This indicates the general tenor of Pohl's results, which have been taken, by some physiologists at least, as confirmatory of Hofmeister's views; the interpretation naturally being that digestive proteolysis in the alimentary tract is accompanied by a rapid production of new leucocytes in the lymph-spaces surrounding the intestine, and followed by a rapid transferrence of the corpuscles from their point of origin to the circulating blood, from which they gradually disappear as their material is made use of in the different parts of the body. In harmony with this view, Pohl finds that there is a much larger number of leucocytes in the blood and lymph flowing from the intestine of an animal in full digestion, than in the arterial blood coming to the intestinal tract. Further, when due consideration is given to all the circumstances attending the circulation of the blood through the abdominal organs, in connection with the great increase in the number of leucocytes during digestive proteolysis, it seems not unreasonable to suppose that some proteid matter might be transferred from the intestine to the blood during the digestive period of six or eight hours. Moreover, if Pohl's views are correct we see that a portion, at least, of the proteid food-product may be transformed into organized material in the body of the lymph-cell prior to its passage into the blood, thus harmonizing with the statement already made regarding the utter lack of proteoses and peptones in the blood and lymph. This obviously means an upbuilding of the ordinary products of digestive proteolysis into the living protoplasm of the leucocytes in the intestinal walls, implying, however, that the transformation is accomplished solely by the leucocytes themselves, and not by the epithelial cells of the intestine.

I have given this brief summary of Pohl's work because it is so closely in harmony with the original views of Hofmeister, and because it offers an easy explanation of one possible way in which some of the products of digestion might perhaps pass from the intestine into the blood. I am inclined to believe, however, that the so-called digestive leucocytosis, which unquestionably does exist, is not a direct result of digestive proteolysis in general, but rather an indirect result, coming from the stimulating action of the nuclein, contained especially in animal cells. Thus, it is a significant fact, as Pohl himself reports, that wheat bread, with its fairly large amount of proteid matter, and which is fully capable of nourishing the animal body, fails to exert any influence on the number of leucocytes in the blood. Yet we know that the gluten and other proteids of wheat flour are converted by digestive proteolysis into proteoses and peptones, with the same general properties as like products of animal origin.

In this connection we may note the experiments of Horbaczewski,[1] which show that nuclein administered to a healthy man will give rise to a very marked increase in the number of leucocytes in the blood. Thus, a few grammes of nuclein may produce as striking a condition of leucocytosis as a large amount of proteid food, due no doubt to proliferation of the lymphoid elements of all the lymphatic tissues of the body. Horbaczewski has reported that the mere injection of 0.25 gramme of nuclein, in the case of rabbits, will cause marked enlargement of the spleen, with striking karyokinetic changes. Hence it may be assumed that, whenever nuclein is set free in the body, leucocytosis may result, provided the nuclein passes into the circulation and is not decomposed immediately after its liberation.

These facts, it appears to me, offer a more consistent line of explanation of digestive leucocytosis than that advanced by Pohl. All animal foods, especially meat of various kinds and milk, contain considerable nuclein or nucleo-albumins, which, by the action of gastric juice, are liberated and partially digested, but the nuclein is certainly not dissolved. Nucleins, however, are soluble in weak alkaline fluids, and when exposed to the action of the alkaline pancreatic juice in the intestine, are in great part dissolved. Thus, Popoff[2] has reported that different varieties of nuclein behave somewhat differently in the intestine, according to their origin. In young and tender tissues solution of nuclein through the alkaline fluids of the intestinal canal is fairly complete, while the older products are somewhat more resistant both to the pancreatic juice and to the putrefactive processes common to the intestine. However, experiments show that the greater portion of the nuclein of ordinary proteid foods is dissolved in the intestine, and absorbed as such in a practically unaltered form. Consequently, passing into the adenoid tissue surrounding the intestine, it has a marked stimulating action on the lymphoid elements, accompanied by a noticeable increase in the number of leucocytes, which are perhaps produced at the expense of a portion of the proteoses and peptones formed during proteolysis.

Thus my interpretation of these results would lead me simply to the admission that, possibly, a portion of the products of proteolysis might pass from the intestine into the blood-current indirectly, through the bodies of the leucocytes formed in the adenoid tissue of the intestine. But even admitting this, we lack positive proof of any direct transformation of proteoses and peptones into the or-

ganized material of the white blood-corpuscles, for it may be that the above products are first transformed through other agencies into serum-albumin, or other like proteids. There are, indeed, many facts which are plainly opposed to any marked absorption and transformation of peptones by the leucocytes of the intestinal mucous membrane. Thus, Heidenhain [1] has severely criticised the theory on the ground that there is very little increase in the flow of lymph from the thoracic duct during absorption, and further that the small percentage of proteid matter in the chyle (about 2.0 per cent.) cannot account for the large amount of proteid absorbed. Further, the objection is made that the leucocytes present in the intestinal mucosa, though numerous, are wholly inadequate to assimilate any large proportion of the ingested proteid food.

Still greater stress, however, may be laid upon the fact that experimental evidence points to the conclusion that lymph-cells cannot assimilate either peptones or proteoses. Thus, quite recently Shore [2] has studied the results following the introduction of a mixture of such products into the lymphatic system by secretion, by absorption, and by direct injection into a lymphatic vessel. Preliminary experiments on dogs showed that when peptone is introduced into the bile-duct it gradually appears in the lymph of the thoracic duct, consequently this method can be made use of as a means of ascertaining the fate of peptone so absorbed into the lymphatic system. The results obtained, using the ammonium sulphate method for the isolation of the peptone, showed that when peptone is injected into the bile-duct with sufficient force to overcome the low pressure under which bile is secreted, there is an increase in the rate of flow of lymph from the thoracic duct. Further, while peptone is somewhat slow in appearing in the lymph it eventually makes its appearance there, in from sixty to one hundred and forty minutes after its injection into the bile duct. A certain amount of peptone naturally passes into the blood, but is then rapidly excreted through the urine. When, however, the renal vessels are ligatured peptone still rapidly disappears from the blood, but then passes into the lymph, and under such circumstances can be detected in the lymph as early as thirty-eight minutes after its injection into the bile-duct. These results, therefore, do not accord with the view that peptones suffer marked transformation by contact with lymph-cells, for when only three-fourths of a gramme of peptone is introduced into the bile-duct, unaltered peptone can be detected in the lymph of the thoracic duct seventy to ninety minutes after its injection.

With reference to the fate of peptone when it passes by secretion into the lymphatic system, it will be remembered that Heidenhain [3] has shown that the injection of peptone into the blood may be followed by a large increase in the rate of flow of lymph. Further, the amount of solids in the lymph, especially of proteids, is considerably increased. From these and other facts Heidenhain is led to the view that the formation of lymph is a true secretion from the blood vessels. Shore finds that when small amounts of peptone are slowly injected into the blood, there is generally only a slight acceleration in the flow of lymph, but the clotting power of the lymph is affected in a remarkable manner. Thus, about twenty minutes after the commencement of the injection the lymph loses entirely its power of coagulating. This continues for about twenty minutes, and then, in spite of the fact that the injection is being continued, the lymph rapidly regains its power of clotting, and finally coagulates quicker and firmer than before. This peculiar action of peptone on the clotting power of lymph may frequently be observed even when the amount of peptone present is too small to be detected with certainty by chemical methods. Thus, when peptone in small quantity is injected very slowly into the blood, the greater part of it escapes through the urine, but a small fraction, sometimes too small to actually detect, passes into the lymph and shows its presence by its peculiar influence on the clotting of the fluid.

When, on the other hand, peptone is injected rapidly into the blood, 0.3 to 0.6 gramme per kilo during two to ten minutes, it may disappear completely from the blood in five to ten minutes after the end of the injection. In such a case, the fall of blood pressure induced leads to more or less arrest of the renal secretion, peptone appearing in large amount in the lymph; but there is no indication of any alteration of the peptone by the lymph, or its contained leucocytes. Thus, when there is no chance for the peptone to escape from the body, as on ligation of the renal vessels, the peptone injected into the blood is rapidly thrown into the lymph, and from the lymph in the tissues of the body it is gradually carried to the thoracic duct, and then again passes into the blood; all of which shows that there is little or no transformation of the peptone by the leucocytes of the lymphatic system.

Further, by direct injection of peptone into a lymphatic vessel, Shore has shown that even so small an amount as 0.049 gramme is not assimilated or transformed by the lymph in half an hour. Consequently, we seem to have strong evidence that peptones are not prone to direct alteration of any kind by the leucocytes of the lymphatic system. Further, it would appear that the lymphoid cells of the spleen are equally unable to assimilate small amounts of peptone injected into the splenic artery. Leucocytes, then, can play no direct part in the absorption of the products of proteolysis from the intestine; the lymph is normally free from both proteoses and peptones, and the leucocytes plainly have no power to transform these bodies into other forms. They can only utilize the proteid material elaborated from the products of proteolysis by other agencies.

Plainly, proteoses and peptones in the blood and lymph are foreign substances. When present in the circulation they give rise, as we have seen, to an increased flow of lymph and to a change in the coagulability of the blood. Further, not only is the flow of lymph augmented but there is likewise an increase in the amount of solid matter, while a corresponding decrease is noticed in the solid matter of the blood-plasma. This fact obviously gives support to the view that the increased formation of lymph after the injection of peptone is due to an active process of secretion by the endothelium cells of the capillary walls.[1] Further, as we have seen, peptone disappears from the blood more or less rapidly after its injection, so that it is quite possible that the loss or alteration of the coagulability of the blood may not be due to the peptone itself, but rather to an altered condition of the blood induced by the peptone. Moreover, this altered condition of the blood may be the real cause of the increased transudation or secretion of lymph so conspicuous after the injection of peptone. Starling, however, by carefully conducted experiments on dogs finds, in conformity with Heidenhain's views, that peptone injected into the blood exercises a direct excitatory effect on the endothelial cells, causing thereby an increased flow of lymph; the increased flow being in no way caused by the change in the blood that is simultaneously produced. Further, it would appear, according to Starling's views, that the change in the coagulability of the blood is not due to the effect of the peptone on the endothelial cells of the blood-vessels, or at least on their lymph-producing functions. Thus, the injection of peptone may result in an action on the endothelial cells of the blood-vessels, thereby increasing the flow of lymph, or on the blood itself with a destruction or diminution of the clotting power of the blood: the two results being more or less independent. Further, the rapid transferrence of peptone from the blood to the lymph is effected by the selective activity of the endothelial cells of the vessel

wall, and according to Starling it is probable that a preponderating part is played by the endothelial cells of the renal capillaries.

In view of all these statements it is very evident that proteoses and peptones once outside the limits of the alimentary tract may be passed about from organ to organ and from secretion to secretion, inducing changes here and there in their course, but suffering very little change themselves. The main efforts of the system are directed to the removal of these unwelcome strangers as speedily as possible, for their marked physiological action renders them somewhat dangerous visitors.

As normal products of digestive proteolysis they are never found beyond the limits of the gastro-intestinal canal, but undergo retrogression in their passage through the epithelial cells of the intestinal wall, being presumably converted thereby into serum-albumin,[1] which can be directly utilized for the nutrition of the body; a conversion which is plainly dependent upon certain inherent qualities of the living epithelial cells and is doubtless of the nature of a dehydration.

Dr. Emmet and Dr. Marion Sims.—At a meeting of the Johns Hopkins Medical Society Dr. Howard Kelly said: "I have been greatly interested in looking over the painstaking work by Dr. Emmet preliminary to the preparation of his book on gynecology. Dr. Emmet occupies a very unique position in the history of gynecology in this country—a position which will grow more and more important as gynecology develops and closer study is given to its history. There has been a tendency, and not without good reason, to give too great prominence to the name of Marion Sims in everything pertaining to the establishment and advancement of original gynecological research in the United States. The striking originality of his methods has largely overshadowed the efficient work of other men, especially that of Dr. T. A. Emmet. Sims's surgery was brilliant, highly originative, and calculated to impress all who visited his clinics and saw him operate. He took up a series of operations, notably that of vesico-vaginal fistula, at a time when the operative treatment was most unsatisfactory. It is a mistake, however, to give Sims the entire credit of the discovery of the operation for vesico-vaginal fistula, as many had carefully studied this subject before and contemporary with him. Among these the able work of Dr. Jobert de Lamballe, of Paris, was especially notable, and if the mortality following his operations had not been greatly increased by diphtheritic infection of the wounded surface, he would undoubtedly have presented a larger percentage of successful results than did Sims. The character of Sims's work was on the whole erratic and spasmodic. Of the enormous number of operations performed by him in the Woman's Hospital, New York, no satisfactory records exist, and for this reason we have only a general, and often an unsatisfactory, knowledge of his methods. Dr. Emmet, following in the footsteps of Sims at the Woman's Hospital, promptly instituted methods of precision in recording operations and histories of cases. His notes were elaborate, scientific, and painstaking, and the book which he afterward compiled from these records is eminently a scientific work prepared by a man pursuing scientific methods. The amount of labor put forth in the preparation of the book is, I think, unexampled in the entire literature of gynecology. It is often said that Dr. Harris, of Philadelphia, is the greatest living medical statistician; he is a relentless investigator, and will search for months, or even years, for a single case. I am accustomed to associate Dr. Emmet with Dr. Harris in this respect, as his painstaking work is seen in the statistical tables, only a few of which appear in his book."

THE EYE-TREATMENT OF CHOREA.

A Critical Review of Certain Factors that may Lead to Spasmodic Diseases, and the Treatment of such Conditions without Drugs.

By AMBROSE L. RANNEY, A.M., M.D.,

NEW YORK.

(Continued from page 555.)

Case VI. *Terrible Attacks of Neuralgia of the Stomach and Persistent Trembling of the Head, Face, and Limbs—Alarming Attacks of Suffocation.*—Mrs. G. ——, aged forty-two. Referred to my care November 10, 1886.

Family History.—Several blood-relatives died of phthisis; father and brother died of phthisis.

History of the Case.—This patient had been for sixteen years a chronic invalid. She was unable to bear the least excitement. Even the companionship of her family for an evening was at times too great a strain upon her nervous system. She was at times a great sufferer from severe paroxysms of neuralgia of the stomach, and frequent attacks of alarming shortness of breath and a sense of impending suffocation would occur. I personally witnessed one of these attacks in my office, and it was entirely free from a trace even of hysteria. It was of much shorter duration than an asthmatic attack, and seemed to be due to a spasm of the larynx. She became markedly cyanotic, and suffered alarming shortness of breath.

In addition to these symptoms this patient suffered for many years from an *uncontrollable trembling of the facial muscles and limbs when at all startled or excited.* She had been for years unable to attend places of amusement or to bear physical exertion.

Eye Defects.—The patient was found to be emmetropic (when under atropine). Esophoria (manifest) of 3° existed; abduction, 5°. A high degree of latent esophoria was disclosed later, with a proportionate decrease in the abduction. Homonymous diplopia at times existed prior to operation.

Treatment and Results.—Much to my surprise (as she had a marked phthisical history) an examination of her eyes showed no refractive error (even when under the influence of atropine). She showed, however, a very high degree of esophoria, and a graduated tenotomy was performed upon both of her interni. The effect was magical. She recovered her health completely within two months, and is to-day able to endure as much as when a young girl. One of the last reports from her, some time ago, states that she had "shopped all day and attended the theatre in the evening." An old friend of the family lately alluded to the case, in my presence, as one "not of cure, but of resurrection."

Six years have now elapsed since the patient was relieved of her "eye-strain." During this period no return of her old symptoms has occurred; nor has she been obliged to resort to drugs for the relief of any physical ailment. At the last tests this patient showed adduction, 33°; abduction, 8°; no esophoria; no hyperphoria.

The preceding case is interesting (from the stand-point of the oculist) in that there was absolutely perfect refraction even under atropine, and that the esophoria was almost totatly latent. The remarkable results obtained by eye-treatment have remained undiminished during a period of over seven years in spite of extreme physical exercise, as compared with her powers of endurance prior to the eye-treatment.

Case VII. *Choreic Movements of the Head, Face, and Limbs, with Recurring Attacks of Gastric Pain, Pallor, and Extreme Weakness.*—Master R——, aged ten years. Referred to me November 10, 1888.

Family History.—Father was for thirty years a sufferer from most extreme attacks of sick-headaches every week, until his latent hypermetropia was corrected. Phthisis

is extremely common among the paternal ancestry, one maternal uncle was insane. Almost all the paternal ancestry have suffered from sick-headache.

History of Case.—This patient was the son of a physician, who had himself been cured of terrible sick-headaches and complete nervous prostration by the correction of a latent error of refraction that had not previously been suspected by himself. The son had been somewhat delicate from youth; being highly nervous and generally anæmic. At frequent intervals severe gastric pain would appear without apparent cause, and create symptoms of extreme pallor and faintness.

When about six years of age, mild symptoms of chorea appeared. The child would twitch and jerk his shoulders, face, and limbs when at all excited. As he grew older these choreic symptoms increased to such an extent as to cause alarm, and to justify an examination of the eyes as a possible factor in causing the chorea. At the time when I first examined the boy, he could not attend any place of amusement without attracting attention by his choreic movements, and at times they were very marked irrespective of excitement. Medication had accomplished nothing. The patient had been frequently removed from school, because it was found that study aggravated the chorea.

Eye Defects.—Under atropine this patient showed a latent hypermetropia of two diopters. Esophoria (manifest) of 4°; abduction, 4°. Later, a high degree of latent esophoria disclosed itself under the influence of prisms with homonymous diplopia. Abduction, 0°.

Treatment and Results.—The child was ordered + 1.00^{s} glasses for constant wear. Three graduated tenotomies were performed upon the interni at intervals of about two months apart, as latent esophoria of a high degree was disclosed from time to time by the patient.

The result was very gratifying. The child recovered completely from his chorea within a year, and has never shown any return.

Within the past five years he has developed into a very tall and strong boy, weighs 150 pounds, and is in perfect health. He uses his spherical glasses now only for study, reading, and any close work for the eyes. He has attended school regularly for the past four years without any ill-effects upon his health.

Case VIII. *Aggravated Type of Chorea Affecting the Face, Arms, and Legs—Marked Impairment of Speech.*—Miss B——, aged eighteen. Referred to me December 1, 1892

Family History.—Mother is very nervous and excitable in temperament.

History of the Case.—This was a well-developed young girl. Up to within a year of her first visit, she had been considered to have a nervous temperament, but had shown no symptoms of chorea. At this time she was allowed by her mother to visit a school friend for a few days. During this visit she participated in various amusements and lived a life different from the routine life which she led at home. On her return from this visit her mother noticed that she was unnaturally excited and extremely nervous. She twitched her arms and face in a very peculiar and unnatural manner, would cry and laugh hysterically, and did not articulate as distinctly as before the visit. These symptoms seemed rather to increase than decrease within the next few days, and caused great alarm to the family. Various forms of medication were tried without benefit during the next few months. The choreic symptoms steadily increased in intensity, and marked physical weakness appeared. She became unable to play upon the piano, could not bear the excitement even of girl companions, and her speech became so thick and indistinct as to become almost unintelligible at times, except to those who knew her well. A walk of one or two blocks would tire her so that she would have to lie down and rest.

At her first visit to my office her choreic movements were very severe in her arms, legs, and face. It was impossible for me at times to understand what she said, as she sputtered and talked as though she had a foreign body in her mouth. No evidence of organic disease could be found, and there was no apparent abnormality in the perception or localization of sensations of touch, pain, or temperature. The power of individual muscles seemed to be intact.

The mother had become strongly impressed with the idea that her daughter was suffering from some organic trouble, and that the prospect of recovery under any treatment was extremely discouraging.

Eye Defects.—Under homatropine she showed hypermetropia, + 0.75^{s}. Her muscular tests were: Adduction, 15°; abduction, 9°; sursumduction, right, 3°; left, 3°; no hyperphoria; esophoria, 1°.

Later on she disclosed quite a high degree of latent esophoria.

Treatment and Results.—This patient showed so little eye defect at the first visit that the case did not seem a favorable one for eye treatment. Prisms were given, however, for esophoria, and increased in strength as fast as she showed any surplus that would justify such an increase. In one week, while wearing 6° of prism, she showed esophoria, 7°, and abduction, 3°. A graduated tenotomy was then performed on the right internal rectus.

Her mother reported the next day that she was better than at any time for a year. Two weeks later, as 7° of latent esophoria had become manifest, a graduated tenotomy was performed on the left internus.

The improvement in the choreic symptoms was noticeable within a week after this operation, and she grew steadily better, so that, at the end of a month, she was apparently well. No choreic movements were noticed, her speech was distinct, she walked several miles daily, could dance and play the piano as formerly.

When last seen, on December 1, 1893, one year from the date of the first visit, there was no return of her old symptoms.

Her eye tests at that time were: adduction, 25°; abduction, 9°; no hyperphoria; no esophoria.

The following case is one that I reported some years ago in my work upon nervous diseases,[1] with two illustrative photographs that showed the changes in expression and the decrease in choreic movements caused by the relief of heterophoria by graduated tenotomies.

I quote this case here because the chorea was very extreme and had persisted for over thirty years, in spite of all therapeutical treatment and the best medical advice.

Case IX. *Chronic Chorea of Thirty-one Years' Duration, Affecting the Head, Face, and all the Extremities.*—Miss D——, aged thirty-three. Referred to me for diagnosis and treatment on May 27, 1887.

Family History.—The father had pulmonary hemorrhages for many years. One paternal aunt died of "hasty consumption." Sick-headaches are very common among both paternal and maternal ancestors. Neuralgia is a frequent complaint among the paternal ancestors.

When two years of age this girl developed chorea. The spasmodic twitchings steadily grew worse, in spite of the fact that her father was a physician, and that she had the services of the most skilful medical men from time to time. The twitchings began on the right side; but they subsequently involved the left side, and also the head and face.

She has suffered some from sick-headaches, as has also her sister. The *hands have gradually become so contractured* that all attempts to use them are more or less distressing. Her fingers could not be extended farther than would suffice to grasp small objects.

When I first saw this patient she was unable to write except by grasping the pencil with all the fingers and the palm of the left hand, and holding the left hand with the right hand as the spasmodic movements of writing were made. She walked with a peculiar, unsteady, and crab-like gait, ate with difficulty, and suffered great pain between the shoulder-blades and over the first lumbar ver-

[1] F. A. Davis: Lectures on Nervous Diseases. Philadelphia, 1888.

tebra (two points, by the way, which are very frequently attacked, in my experience, when eye-strain is present). She had never written with ink. Prior to menstruation (which occurred at seventeen years of age) the patient had experienced attacks (probably epileptic) which she describes as "those of numbness, followed by a loss of consciousness." She has had chronic constipation all her life. The memory and mental faculties are perfect.

When I first saw this patient the spasms were very violent, especially about the face and neck. The limbs were jerked about, the fingers too tightly clinched at times to grasp anything, and the speech was rendered peculiarly spasmodic and almost unintelligible at times. She sputtered, and frequently ejected drops of saliva when endeavoring to converse.

Eye Defects.—At the first examination she exhibited no refractive error; but under atropine a high degree of hyperopia (1.75 D.) was detected, and spherical glasses (+ 1 D.) were at once provided. In order to test her eye muscles, the services of Professor J. Williston Wright, of New York City, who saw her with me by invitation, were invoked to hold her head. This he did with no small effort by clasping the head on either side, and firmly pressing her head against his body as he stood behind her chair. During this examination she whistled shrill notes on two occasions, and underwent the most violent facial and body contortions.

Treatment and Results.—The results of this imperfect examination (necessarily so under such conditions) indicated to me that a high degree of hyperphoria existed; and as I could not again see the patient for some months, I decided to perform a free but incomplete division of the left inferior rectus muscle. I then instructed the patient to try and get a photograph taken, if possible, before she saw me again. She laughingly said that she had never been able to have a picture taken, but she would do so if she could. She then departed for home with instructions to return to me for treatment in the autumn. The first picture received of this case was one that she was able to have taken three weeks after the operation, when her head and shoulders had become comparatively calm, as a result of the relief afforded by it. This photograph was deemed at that time a great success by herself and friends. In it the blurred outlines which indicate that the movements were still somewhat active, are very apparent.

During the next autumn this patient was under my care for some eight weeks. I partially divided the right superior rectus and both externi in order to overcome a high degree of left hyperphoria and exophoria, and I administered static sparks daily to the spine and limbs. A second picture that I possess gives, better than words can describe it, an idea of the wonderful improvement which has taken place. Prior to her departure for home she could thread the finest cambric-needle, and pass her fare to the conductor of a street car without attracting the notice of passengers, or throwing it out of the window, as she certainly would have been apt to do two months previously. She could fully extend her fingers, walk several miles a day, write with far greater certainty and ease, and eat at a boarding-house table without exciting comment. Her limbs still twitch somewhat immediately before going to sleep, and, in the presence of strangers or when unduly excited, she still shows some spasmodic movements of the face and shoulders. When calm she is, however, perfectly composed, and almost entirely free from convulsive movements. She considers herself as practically cured; but I suspect that time and some further operative work upon the eye-muscles will be demanded before complete restoration to health is effected.

During the past seven years this patient has not been able to come to New York to complete the work that I began upon her eye-muscles. She has, however, improved steadily in her physical and nervous condition. She writes me several letters each year, in ink, and reports that she continues to be practically free from all chorea, although still somewhat nervous when tired or excited.

As I regard this case as one of the most distressing and typical cases of chronic chorea ever reported, it may be well to state that the patient is well known to Professor A. M. Phelps, M.D., and Professor J. W. Wright, M.D, of this city, and Professor Woodward, M.D., of Burlington, Vt. She has also been seen by many members of the profession, both from this city and distant States, during her treatment in my office.

During the whole treatment of this patient no drugs have been employed, and the photographs that I published in my work on nervous diseases are from untouched negatives. I attribute to the static applications the rapid relief of the contractured state of the fingers and the improvement in her general strength; but, from many facts observed during my treatment of her, I am convinced that the relief of the eye strain is alone deserving of whatever credit may be claimed for her recovery. Four weeks before she was dismissed from my care she read and sewed continuously for several days, and was immediately precipitated into a relapse, which as rapidly subsided when the cause was ascertained and its recurrence prevented.

Case X. *Extreme Chorea, Accompanied with Complete Nervous Prostration that Entailed a Retirement from all Business Pursuits.*—Mr. L——, aged thirty-five; married; manufacturer. Referred to me November 19, 1892, by Dr. E. W. Hedges, of Plainfield, N. J.

Family History.—Father died of phthisis, and mother of some kidney disease. Patient has six children, all living and well.

History of the Case.—In February, 1892, the patient had a "collapse" while at his office. His face flushed, his head was confused, he was unable to attend to any business, and had to be taken home. He gave up his business, tried various tonics, change of air, etc., but was not materially improved.

At the time of his first visit to me he was absolutely unable to attend to any business; the least excitement disturbed him; he had pain in back of the head and eyes, and had marked choreic symptoms. His gait was jerky and very uncertain from loss of control of the leg muscles. Walking tired him greatly, although he was a strong and robust-looking man. His face was in constant motion and his speech very much impaired. It was with difficulty that he was kept quiet long enough to test his muscles and eyes.

Eye Defects.—Under homatropine he showed hypermetropia and astigmatism; O. D. + 1.25^{s} O. S. + $0.75^{s} = + 0.50^{c}$; axis, 90°. His muscular tests were: adduction, 20°; abduction, 6°; no hyperphoria; esophoria, 2°. Later he disclosed a very high degree of latent esophoria.

Treatment and Results.—All drugs were discontinued. Glasses were ordered for constant wear as follows: O. D. + 0.50^{s}, O. S. + 0.50^{c}, axis, 90°. Prisms were given for relief of his esophoria at first, as he disclosed esophoria to a high degree very rapidly. Graduated tenotomies were performed upon both internal recti within two weeks. During the next four months each internus was again button-holed.

The improvement in this patient was quite marked within a few weeks after the first two tenotomies. He was much more quiet, could walk steadily without fatigue, his speech was normal, his choreic movements had almost entirely disappeared.

In May, 1893, he had a slight return of his old symptoms after excessive use of his eyes, and was given prisms for relief of some remaining esophoria.

When seen in September, 1893, he was feeling well and attending regularly to his business. Since January, 1894, the patient has disclosed some latent hyperphoria. This is still under observation. The patient has improved sufficiently to resume control of his former business, and exhibits very few of his old choreic symptoms.

Case XI. *Chorea of Facial Muscles and Limbs, of Three Years' Duration.* — Master A——, aged eleven. Referred to me October 22, 1890.

Family History.—Mother had severe sick-headaches,

until relieved by the correction of hypermetropia and esophoria under my hands. Father had chorea until seventeen years of age, and has always been very nervous. He was operated upon for exophoria by me, with decided benefit.

Phthisis is common among both maternal and paternal ancestry. Chorea is common on the mother's side. Paternal relatives are very nervous, and one aunt has St. Vitus's dance.

History of the Case.—When this patient was a baby he had catarrh of the stomach, and has had a weak stomach ever since. When three years old he began to have "twitchings," which gradually grew worse, and have continued without intermission ever since. The choreic movements are noticeable in the extremities, but especially marked in the face.

Eye Defects.—Under homatropine he showed: O. D. + 0.50^{s}; O. S. + 0.50^{s} = + 0.50^{c}, axis, 90°. His muscular tests were: adduction, 16°; abduction, 7°; sursumduction, right, 3°; left, 3°; no hyperphoria; esophoria, 1°. After wearing prisms for several weeks he disclosed considerable latent esophoria.

Treatment and Results.—A 1° prism was given for esophoria, and increased in strength as fast as he showed any surplus over the prism. Two months later, a graduated tenotomy was performed on the left internus A full correction for his refraction was also given for constant wear.

For some weeks after this operation there was a marked improvement in the choreic symptoms, but a relapse soon occurred, and esophoria prisms were again put on with marked benefit.

February 26, 1891.—Ten weeks after the first operation, the right internus was divided.

March 5th.—Patient showed no choreic symptoms and looked like a different boy.

His muscular tests are: adduction, 32°; abduction, 8°; no hyperphoria; esophoria, ¼°.

Since last note this patient has been relieved of all choreic disturbances as far as is known.

Case XII. *Chronic Chorea with Marked Impairment of Speech and great Difficulty in Walking.*—Miss R——, aged thirty-five; teacher; referred to me December 27, 1893.

Family History.—Father was myopic, and suffered with headache. Mother had St. Vitus's dance for years, and died from it.

Three brothers and one sister have headaches and wear glasses. One cousin on each side is in an insane asylum.

History of the Case.—When a child, this patient suffered from headache. For seven years patient worked very hard at teaching, and suffered from stomach trouble.

In May, 1892, she broke down completely with nervous prostration and chorea. She could talk but little, and that with difficulty. Her limbs were so much affected that she could hardly control them enough to walk. She was sent to Colorado for a year, returning in July, 1893, not much improved.

At the date of her first visit to me, she walked with difficulty. Her speech was very slow and jerky; and her sister states that her mind is failing very noticeably. There is a fine tremor of the muscles which is felt wherever she is touched, but no marked convulsive movement.

Eye Defects.—Under atropine she showed hypermetropia and astigmatism; O. D. + 0 25 = + 0.25^{c}, axis, 90; O. S. + 0.50^{s} = + 0.50^{c}, axis, 90. Her muscular tests at the first examination were: adduction, 16°; abduction, 4°; no hyperphoria; esophoria, 2½°. Within two days, however, while wearing 6° prism, she showed 8° of esophoria, with unconquerable homonymous diplopia. Later on she disclosed a high degree of latent esophoria.

Treatment and Results.—Glasses were given for constant wear to correct her astigmatism, and within a week a graduated tenotomy was performed upon each internal rectus.

She began to improve soon after these operations; was much quieter; talked better; slept well; and began to walk regularly every day. As more esophoria became manifest, prisms were given and gradually increased in strength Two weeks after the first operation a graduated tenotomy was again done on the right internus.

One week later her tests were: adduction 26°; abduction, 6°+; no hyperphoria; esophoria, 1°.

At this time she reported that she was sleeping eight hours every night, walking from two to eight miles a day, and feeling much less nervous. She talked naturally, unless unusually excited, and controlled her limbs perfectly. She was allowed to return home, with instructions not to begin any eye-work for at least three months.

The change in the facial expression of this patient, as well as in her walking, talking, and general demeanor, that had occurred in less than six weeks, were so marked as to excite the greatest surprise among those who had met her when suffering from her nervous malady.

Although I do not yet regard the latent esophoria in this case as fully corrected, still the physical condition of the patient had so improved that I deemed it best to wait several months before any further investigation of her remaining heterophoria.

156 Madison Avenue, February 15, 1894.

FURTHER CONTRIBUTION TO THE STUDY OF OCCIPITO-POSTERIOR POSITIONS OF THE VERTEX [1]

By S. MARX, M.D.,

NEW YORK.

In the light of the increased experience which the last two years has afforded me, I venture to approach you with a subject which is ever interesting to me. I shall not burden you with quotations from authors or standard works. These shall be entirely omitted, since the following lines shall be a *résumé* of cases for the last two years, occurring in private and consultation work, and the deductions as to treatment which I have based upon them. Certainly, therefore, a paper upon the management of these cases, according to my experience, must of necessity carry with it a considerable amount of dogmatism. To consciously claim such is not my intention, but rather to give you what appears to me to be the proper lines of treatment in these most unwelcome cases; for unwelcome they are. Of the gravity of these cases the more I see of them the more I am led to look upon occipito-posterior positions as the most aggravating and complex cases we, as obstetricians, have to deal with. And why so pessimistic? Why should such a head presentation, apparently normal, for we are taught to regard them as such by many writers who hardly accord them a thought or a place in text books, carry such gravity with it? One reason is sufficient. They do not occur frequently and are so seldom recognized by the general practitioner, and even sometimes not by the specialist, that early, or, if you choose, timely interference has been neglected or lost. The diagnosis by the ordinary methods, I again maintain, is, in not a few cases, difficult, sometimes impossible.

As experienced an observer as Nagel, of Berlin, states that in some cases a diagnosis by internal examination is impossible on account of the large caput. External examination, especially when we are called late, reveals nothing but the presence of the fœtal heart. Small or large fœtal parts cannot be mapped out, owing to the constant state of uterine contraction. Abdominal palpation, so highly lauded by some obstetricians, has proven in my hands in not a few cases an absolute failure. I have on a number of occasions diagnosed with as apparent an ease "as falling off a log" a typical occipito-

[1] Read before Section of Obstetrics, Academy of Medicine, March 29, 1894.

anterior position of the vertex, and yet, when the pains seemed to lag and something appeared to me to be wrong, chloroform narcosis and the introduction of the aseptic hand entirely within the uterus, or the palpation of the ear, a posterior occiput at or above the brim has been the result of such an examination in some cases. Surely I can lay claim to possess the ordinary average *tactus eruditus*, but I am honest to admit that in not a few cases abdominal palpation, at least in my hands, has proven a failure, so far as diagnosing the position of a given presentation is concerned. Abdominal palpation certainly has value in assisting us alone, or, plus the ordinary methods, to diagnose presentation; but of what value is this? Yet, in the light of my own experience, abdominal palpation seldom assists us in diagnosing position, and therefore, for me, has very little value. Where we are in doubt the introduction of the full aseptic hand can do more to clearly convey to our minds the position of the presenting part, and the condition in general of the maternal parts, both soft and bony, the size of the fœtal head, than both vaginal and abdominal examination, either singly or combined. I am free to admit that many cases can be diagnosed by suture and fontanelle. A presumptive diagnosis can be made, and this is the case especially in primiparæ, when there is slow engagement or when the head remains high above the brim; or when the head is in the pelvis, vaginal examination reveals the pelvis well filled behind by the larger end of the occipital globe; further, by the character of the pains, which are unsatisfactory. They are short and nagging, consequently the first stage is very tedious. A cardinal rule, and one ever to be thought of is: Never apply the forceps until the position has been accurately made out by the introducing of the half or full hand. Again, the cases are grave, because we are often called to them late, so late that little short of delivering a dead fœtus is necessary.

On two occasions I distinctly call to mind, I have been called when the uterus was tetanic, the waters had long escaped, the child apparently dead, and have been asked to attempt to deliver when nothing but a perforation could have been thought of. In another case, by actual count by the husband, the forceps had been applied twenty-three times by three different physicians, and when they from sheer exhaustion allowed me subsequently the privilege of being the fourth, an occipito-posterior at the brim was only to be recognized when the hand was introduced into the uterus. Version was then instituted and the patient easily delivered.

In my last article on this subject, written in February, 1892, and published in the *Journal of Obstetrics*, the extreme rarity of these cases was commented upon; this, my later experience, has taught me to be incorrect. My belief to-day is, that they are of more frequent occurrence than we are led to believe. Since the last twelve months I have met with six or more persistent occipito-posterior cases. In the treatment of these cases it must be remembered that perfect flexion of the head, that is, approximating chin and sternum, is a *sine qua non* in influencing and furthering rotation. Where, as is often the case, the failure of flexion is due to a dolicocephalic skull, abnormal flexibility of the spine, and so on, continuous pressure on the sinciput is all that is necessary in many cases. To keep the head flexed, to overcome a uterine obliquity, postural treatment is often all that is further necessary. Placing the woman well over on the right or left side, corresponding to the right- or left-sided position of the occiput, has, in my hands, proven to be one of the most valuable means of influencing rotation. When, in spite of flexion (manual) postural treatment, the patient is unable to deliver herself on account of the failure of rotation, some other form of interference must be instituted.

To analyze this subject more carefully, we must study the position of the head, successively, above the brim, fixed at the superior strait, in the pelvic basin, and on the pelvic floor at the outlet.

I. **The Head above the Brim.**—In spite of the very clear and almost convincing essays of some modern obstetricians, advocating manual rectification of the head, that is, rotating the head by the hand into an anterior position, I have repeatedly and conscientiously tried this method, as the gentlemen who witnessed the attempt can testify, and have never yet once succeeded, even when the attempt was made under deep surgical chloroform anæsthesia. The head would rotate with surprising ease, but when the hand was removed and an attempt made to deliver, the head would be found again in the posterior position. Whether the failure to accomplish this much-wished-for rotation was due to a faulty technique or not, or whether it was due to the fact that I was unable at the same time to rotate the body of the fœtus, I am unable to say. Yet I consider this method faulty for the following reasons: 1. Inability to cause rotation, which experience was afforded me in at least six cases. 2. The necessity, in the event of failure of the method of manual rectification, of reintroducing the hand in the uterus and of doing the only other thing to be done under the circumstances, namely, a version. 3. In the event of failure, the loss of time entailed, and, what is essential to the easy performance of a version, the escape of the amniotic fluid. Nevertheless, since it has been done, and done successfully, this method is certainly worthy of trial.

My personal predilection in these cases is to deliberately elect the operation of complete version, which when done early is simple of performance. When the operation of version is done late, after the waters have escaped, and the uterus is closely hugging the fœtus, it is just as easy of performance, if not easier, than manual rectification of the head.

II. The Head Fixed at the Superior Strait.—My success in these cases, though limited, has been brought about by the application of the Tarnier axis-traction forceps. There are many skilled obstetricians who would not listen or countenance the application of the high forceps in any case. By the high forceps we mean the use of that instrument to the fœtal head, whose greatest segment is already engaged in the superior strait, consequently pretty fairly fixed. Yet we are told by some that the true high application of the forceps should never be done, and is seldom if ever indicated. With such a position of the head, version is deliberately elected. My experience with the Tarnier forceps, minus the perineal curve, has been eminently satisfactory. With the ordinary forceps in action, we must of necessity influence moulding, rotation, and descent of the head, through our purchase upon the handles by traction and pressure upon the head. This is not so when the Tarnier instrument is in use. Here the handles of the instrument are let alone. They are used simply, and act mainly to show as an index of the position of the head and the direction in which we are supposed to make traction. Our extraction force is directly applied to the cross-bar of the traction rods, which is used to drag the head uninfluenced through the pelvic canal, so that rotation can occur in due time, as it does in the greatest majority of cases. Therefore, the great advantage in using axis traction is the free mobility of the forceps when applied to the head. In the ordinary forceps the mechanism, as compared to the pelvis does not come into operation, while in the Tarnier forceps, the head, together with the body of the instrument, obtains great freedom in mobility. But it must be remembered that rotation, in the largest majority of cases, occurs at the pelvic floor. This is due to the resistance offered by the perineal structures, and further by the turning-points afforded by the ischial spines, especially when they are prominent. When the performance with the Tarnier instrument has been successful, we find the blades rotating with the head, so that in a short time they are placed inversely, as Pajot would have us apply them in persistent posterior cases, while we are making traction by means of the cross-bar. If, as sometimes occurs, we are unable to lock the blades, or we are

unable to approximate the handles, so that we are threatened with instruments which will surely slip, a version performed is our only hope, provided manual rectification, which should be tried, fails.

III. Head in Pelvic Basin.—When the occipit is behind and in the pelvic basin, the attempt should be made to rotate the head in a natural manner by the application of the Tarnier instrument. Should this fail, a forcible rotation with forceps, which I instituted in two cases, and with success, might be attempted. In one case I rotated with a Simpson's forceps and got, as a result of using an instrument with a marked pelvic curve, a vaginal tear, which fortunately healed promptly after a continuous catgut suture. In the other case a pair of short, straight forceps was applied, like those used for lifting the head over the perineum, and the head was easily rotated into the anterior position and delivered without any trouble. Therefore a forceps with a pelvic curve, especially a marked pelvic curve, materially hinders a rotary movement and predisposes the possibility of a tear of the vagina.

IV. Head Low Down Upon the Pelvic Floor. — These cases must as a rule be delivered as posterior cases, where delivery is at all possible, or the attempt might be made to forcibly rotate the head into an anterior vertex. Where the delivery by the forceps, of the posterior vertex cases as such, is undertaken, my preference is for a pair of short, straight forceps. Traction should be made in the second position until the root of the nose can be felt under or directly behind the pubic arch. The forceps should now be removed and applied so that it adapts itself accurately to the head and does not project beyond the head for even a short distance. Where the forceps tips project beyond the head the rapid passing of the handles from the second to the third position, in my opinion, is a frequent cause of lacerations of the vagina and rectum which extend high up. A finger in the rectum informs us of the exact position of the blades. After reapplying the forceps the handles are rapidly lifted directly in the third position so as to cause over flexion of the head and thus liberate the occiput. Flexion can be furthered by pressure with the thumb against the anterior head and one or two fingers of the same hand in the rectum, assisting in lifting the occiput over the perineum. Where delivery is impossible, on account of impaction, by any of the other methods, the only course left open to the accoucheur is a perforation, or, as has been lately done by Murray, where the child is alive, a symphyseotomy, an operation which can be readily done, and the consent easily obtained in a well appointed lying-in institution. But how different it is in private practice, where I doubt whether the consent could ever be obtained in order to do an operation whose rate of maternal mortality by the best operators is anywhere from six to ten per cent .

In finishing, the attention is called to an atypical form of occipito-posterior position, which though of rare occurrence has personally come under my observation on two occasions, namely, true occipito-sacral positions of the vertex above the brim, the sagittal suture conforming with the true conjugate of the inlet ; in these cases the occipito frontal diameter of the fœtal head of 12½ ctm. attempting an engagement through the pelvic inlet, whose conjugata vera normally is about 11.0 ctm. Singularly, in both cases the women had fairly typical, generally contracted pelves, contracted to the extent of from 2 to 4 ctm. in all diameters. On account of the pelvic contraction, no other measures were instituted, but deliberate version was performed, the after-coming head being carefully guided through the largest diameter of the pelvic inlet, namely, the transverse. The children were unusually large, and in both cases the version extremely difficult. Symphyseotomy in one case was advocated, the true conjugate being about 9 ctm. The operation was absolutely refused. In cases of this class, where the pelvis is apparently normal, a partial manual rectification should be attempted, so as to bring the sagittal suture to conform with one of the oblique diameters of the inlet, thus making the position a true right or left occipito posterior, or the case could be converted into an anterior position by complete manual rectification. Should both fail, nothing but a podalic version can be performed.

1111 Lexington Avenue.

PRACTICAL AND EFFICIENT STERILIZATION OF MATERIALS FOR PRIVATE OPERATIONS—THE FINISHED PORTABLE STERILIZER.[1]

BY WILLY MEYER, M.D.,

NEW YORK.

PROFESSOR OF SURGERY AT THE POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, ATTENDING SURGEON TO THE GERMAN AND NEW YORK SKIN AND CANCER HOSPITALS.

Practical and efficient sterilization of materials for private operations may be divided into two classes, according to the doctors who make use of it.

I. Sterilization in the hands of those who prefer to always render materials aseptic "at their own home," and then take it along in their satchel prepared for the operation.

II. Sterilization by those who also prepare the materials which are to come in immediate contact with the wound "at the patient's home," immediately before the operation.

I. Sterilization at home. How can these doctors proceed ?

1. Boiling.

Instruments: They can boil their instruments for five minutes in any vessel: pot, fish-boiler, Rotter's apparatus, etc., according to their convenience. They will use a 1 to 1½ per cent. soda solution. This is the only recommendable and proper method of sterilizing instruments.[2]

Gauze, silk, drainage-tubes, etc. :

If they have more time at their disposal and do not want to buy a sterilizer, they may even "boil" at home the gauze which had been cut before and folded into compresses of proper size. They will do this in plain water, or better, perhaps, also in a 1 to 1½ per cent. soda solution, in an ordinary clean pot for half an hour. Then the gauze is dried. It will be reliably aseptic beyond doubt. But the boiled and dried gauze has lost a good deal of its original softness and pliability. It is less absorbent. Silk or linen-thread rolled on glass-spools may be boiled for half an hour in a five per cent. solution of carbolic acid or one per cent. soda solution, and then preserved in alcohol. Rubber drainage-tubes should be boiled in soda solution and then preserved in an antiseptic lotion.

The procedure of sterilizing material for the dressing in boiling water is extremely time robbing. We therefore will rarely find the method of boiling used in private practice for the sake of rendering aseptic anything else than the instruments, silk (antiseptic preparation), and drainage-tubes.

2. Dry heat.

Can the doctor who prepares his materials at home use dry heat for his purposes? Will it be practicable for him to, as it is often called, "bake" his instruments, gauze, etc. ? I believe not. Experiments of Robert Koch, of Berlin, made in 1880, have demonstrated :

(1.) Ordinary cocci are destroyed in a temperature of a little more than 212° F. (100° C.) after an hour and a half ; a temperature of 284° F. (140° C.) is needed for three hours, and one of 302° to 356° F. (150° to 180° C.) for two hours.

[1] Read before the Section on General Surgery of the New York Academy of Medicine, March 12, 1894.

[2] Knives do not stand boiling for any length of time. Their edge becomes dull at once. A few seconds' boiling will suffice to destroy the ordinary infectious cocci. Knives should be rubbed with a piece of sterilized gauze which has been soaked in alcohol or ether. Besides this, their blades might be dipped for a few moments into the boiling soda solution.

in order to kill anthrax spores. (2.) Objects exposed to hot air in an apparatus are unequally penetrated by the same. A small bundle of clothes, for instance, was found not to be thoroughly disinfected after having been baked in a temperature of 284° F. for three to four hours. (3.) Almost every sort of material is more or less damaged by this mode of disinfecting.

It is further a well-known fact that our instruments are spoiled by the repeated effect of the intense dry heat; they become forever soft and dull (steel-iron is changed into rod iron); they also rust. Dry-heat sterilization has been a failure, and therefore lost its place in practical surgery. There is only one exception, viz, the preparation of catgut. The chemical sterilization of catgut is tedious. It takes two and a half days, twenty-four hours in ether or benzine, twelve hours in alcohol, twenty four hours in sublimate water (not in sublimate alcohol), 1 to 1,000; preserve in alcohol. In hot air of 302° F. (150° C.) it can be reliably rendered aseptic in forty-five minutes (Braatz). The process takes practically an hour and a half, as the apparatus needs three quarters of an hour before getting up a temperature of 302° F. Of course a special apparatus is needed for the purpose. Braatz has constructed a very handy one. He first extracts the fat of the gut with ether. I am able, through the courtesy of Messrs. R Kny & Co., of this city, to demonstrate the apparatus devised by Braatz here to-night.[1] (Demonstration.) The gut is best rolled on glass spools before sterilization, and then preserved either dry in special small metal boxes constructed for the purpose [2] or, perhaps, more practically for private use, in alcohol.

I am indebted to Dr. Edebohls, of this city, for calling my attention to a small sized, not portable, sterilizer, which had been recommended to him as very practical by Dr. Max Schüller, of Berlin.[3] It is here before you to-night. The apparatus can be used for sterilization by steam and dry heat. In it the catgut is put as bought, rolled on glass spools, and the fat is not extracted first. Yet the material is absolutely sterilized after three to four hours, as Dr. Edebohls asserts.

In all other respects dry-heat sterilization—baking—has to be given up in practical surgery on account of its being an unreliable, time-robbing, and (to the material) harmful procedure, and infinitely inferior to the third method of sterilization which the doctor can make use of at home:

3. Steaming.

Any reliable apparatus can be used. For surgeons and gynecologists that of Braatz,[4] or the one made by Lentz, of Berlin, mentioned above, deserve recommendation. The one recently devised by Boeckmann, of St. Paul [5] also seems to be quite practical.

The cheap Arnold sterilizer will receive all the materials which come directly in contact with the wound, and, moreover, aprons. The apparatus does not permit of boiling the instruments, however. Another vessel must be used for this purpose. (Instruments should never be steamed, because they rust; the procedure also consumes an unnecessary long time—twenty to thirty minutes.) If my portable sterilizer be on hand, aseptical preparation of everything needed (catgut excepted) will take half an hour. Of course the materials having been steamed can be left in those sterilizers, which are portable (Arnold's, author's), and carried in and with them to the patient's home, ready for use.

If you ask me, Mr. Chairman and Gentlemen, "Is sterilization at the doctor's home efficient, without using a portable apparatus?" I have, of course, to say: It is, provided gauze, drainage-tubes, silk, cotton, etc., are first specially and tightly wrapped in a piece of gauze or a towel held by pins, and thus put into the sterilizer. Afterward everything must be transferred "within the same cover" into the doctor's satchel, which is opened at the patient's house only, after proper disinfection of the hands. Or the material has to be carried along in the metallic perforated trays which had received it for the act of sterilizing, and are now, for the sake of transportation, surrounded by a leather- or canvass-cover with handle. If this care were not taken, the doctor always had to thoroughly disinfect his hands at home before handling the material lest contamination should take place. Since we know that air-infection is practically *nil*, and that contact infection means everything, we have to lay more stress on the reliably aseptic condition of all material which is going to come in contact with the wound in the course of the operation, besides fully disinfecting our hands. The latter can never be done too carefully. A doctor who is careless in this respect, before and during the operation, is bound to have failure after failure, even with the most perfect sterilization of all the materials.

If you ask me, "Is it practical for a doctor to always sterilize materials for private operations at his home, and then to carry it with him in his satchel?" I decidedly answer, No.[1] It means, to say the least, a waste of time, and is apt to prevent a rapid introduction of aseptic surgery in private practice on account of complicating the procedure. If he employs a private nurse who has charge of all the preparations for the operations, this point may be less important. And yet, if the package containing gauze or anything else should drop on the floor at the patient's home, what then? Or if one or the other instrument drops down, and a clean vessel for reboiling is just not at hand? I believe that doctor would at the next occasion do what is preferred by the second class of operating physicians, namely:

II. To have a sterilizer, which also permits of rendering aseptic the materials which are to come in immediate contact with the wound, "at the patient's home," immediately before the operation, which is, in one word, "portable."

According to my opinion a portable sterilizer should answer the following purposes:

1. It must be portable, that is to say, not too clumsy, not too heavy, yet large enough to receive the longest instruments in use. For the sake of easy transportation an ordinary canvas cover, with round leather handle, or, if wanted, a more elegant leather-case, will prove very convenient.

2. It must permit of sterilizing everything needed for the operation as such (instruments *and* materials [catgut excepted]) within the same apparatus.

3. It must be practical, that is to say, it must contain everything necessary for sterilization within itself.

Therefore:

a. It must have its own lamp.

b. It must be constructed on the assumption that warm water is not always at hand at the patient's home.

c. Measuring of the necessary amount of alcohol for the lamp and of water for the apparatus must be avoided.

d. The sterilizer must do effective and reliable work in as short a time as possible, and without needing attention with reference to the proper time; in other words, it must as far as possible be "self acting."

Has a sterilizer of this kind hitherto been at our disposal? I believe not.[2] The one constructed by myself

[1] It is made by Schmucker, of Heidelberg. See E. Braatz, Grundlagen der Aseptik, p. 29.

[2] Braatz: l. c., p. 31.

[3] Manufacturer: E. A. Lentz, Berlin, 36 and 37 Spandauer St. See Catalogue, No. II.; Abtheilung III., 1893, pp. 108 and 109.

[4] L. c., p. 62.

[5] New York MEDICAL RECORD, 1894, No. 1, p. 30.

[1] With reference to silk or linen thread, a "specialist" who is going to do a more serious operation—intra-abdominal, resection of joints or bones, amputation, etc.—will do best to attend to the preparation of the necessary different sizes at home and take them with him (as the catgut) ready for use. Yet it can, if wanted, always be thoroughly sterilized immediately before the operation within the same apparatus.

[2] As mentioned above, the rather clumsy, round Arnold sterilizer, which is of inferior make, can be put in a cover, with handle, and thus made portable. But instruments cannot be boiled in it. Another vessel is needed for this purpose. It is made of tin, which easily rusts. Its use requires timing the act of sterilizing. The so-called "Van Heusen's Compress Heater and Sterilizer" is, in its present shape, not recommendable for the use of the operating physician as a portable apparatus. The tray of its largest size is too small to receive all the material that is needed for a major operation; instruments can-

which I shall afterward take pleasure in demonstrating once more before the Section,[1] according to the suggestion and request of our esteemed Chairman and Secretary, seems to fulfil the above requirements. It is, I believe, practical and worthy of a thorough trial. It will be of special value in operating out of town.

Before showing the apparatus in its present finished shape I have to answer two questions: 1. How many minutes are actually required to thoroughly sterilize gauze, etc., in a portable, that is, in a not very large apparatus? 2. Is it an essential feature of sterilization to warm the materials before and after the procedure (so called "Vor und Nach waermen" (Schimmelbusch))?

First question: How many minutes are actually required to thoroughly sterilize gauze, etc., in a portable, that is, in a not very large apparatus?

Answer: The strictest proof would be given in the following manner: Let anthrax spores dry on a woollen or cotton thread; wrap it in a few yards of gauze, this again in a towel as tightly as possible; put it at the bottom of the tray for the materials to be sterilized; make out after how many minutes the spores are destroyed. I had neither time nor opportunity to try this with my steri!izer, and believe the experiment to be superfluous, since Schimmelbusch has made the same with a small-sized apparatus of his own device. In it the steam also is generated, as in my sterilizer, from boiling soda solution, which boils at about 219° F. (104° C.). He found, in experiments with reference to killing anthrax spores and disinfecting dressing materials which had been saturated with pus, certain death to all micro-organisms within fifteen minutes in every instance. Without giving reasons for it, he nevertheless puts thirty minutes as the proper time for sterilizing gauze in his apparatus. Braatz remarks, in explaining the proper handling of his portable sterilizer:[2] "All objects to be sterilized by steam are left in the same for about twenty minutes, counting from the moment the water boils thoroughly." And on p. 139 he says: "The objects remain in the apparatus for half an hour, in the small pot (p. 135) at least one quarter of an hour after steam is in full generation. Then everything is absolutely sterile and more trustworthy than it might be accomplished with a strong antiseptic in days, with a five per cent. carbolic solution in weeks." Fifteen to twenty minutes, therefore, is the time which is absolutely needed to completely sterilize the materials for an operation in a comparatively small-sized (portable) sterilizer. In my sterilizer twenty-four minutes are given to thorough steaming if two quarts of cold water be poured into the kettle. If hot water be on hand and can be made use of at once when starting the apparatus, anxious minds will be able to increase the time for sterilizing to twenty-eight till twenty-nine minutes.

Second question: Is it an essential feature of sterilization to warm the materials before and after the procedure?

Answer: Not at all. Erwin von Esmarch has shown by careful experiments (1888), that the disinfecting power of the steam is increased in proportion to its moisture. Warming the material, before it is reached by the steam, is therefore not only unnecessary, but actually reduces the disinfecting power of the steam. This in its principal wrong construction (primary warming) is also found in the well-known Lautenschlaeger's steam-sterilizer. Too much stress, furthermore, has been wrongly laid upon the necessity of a dry condition of the steamed (aseptic) gauze, "the drying after steaming." Aseptic (steamed) gauze, which, say, is moistened by some condensed steam, is absolutely harmless and perfectly reliable. The direct application of moistened steamed gauze to a wound will certainly never involve a risk for the patient. Nevertheless we can try to prevent moistening the superficial layers of the gauze in a portable sterilizer, and can easily do so by spreading a towel on top of the material, in order to prevent dripping of some condensed water from the lower aspect of the lid.[1] What we have to emphasize however, is this: The dictum that preliminary and after-warming of the gauze is "a material factor" in properly sterilizing the same, is wrong and untenable. It tends to obstruct simplifying aseptic surgery.[2]

Additional points of my finished portable sterilizer which deserve mentioning in comparison to the one described in the MEDICAL RECORD of March 3d are:

1. The Bunsen burners are wider. The quantity of alcohol consumed in one half hour is a little increased for this reason, = 420 c c. (14 ounces), instead of 400 c.c. Its lid has a movable wire handle on its upper, and a cover of pressed asbestos on its lower aspect. This permits to extinguish the lamp at will with absolute ease and safety.

2. The stand is made of galvanized iron. It will thus be less easily blackened by the flame.

3. Each apparatus contains a plate of pressed asbestos, which could absorb all the 420 c.c. of alcohol. The plate is put underneath the lamp. With it sterilization may be done on a polished mahogany table without causing any damage to the same.

4. The lid of the outside kettle fits more tightly. The continuous slight loss of steam is thus greatly reduced.

In conclusion, I want to draw the attention of the profession to an important question. It is all right and good, also profitable, that the operating physician should have a sterilizer of his own, portable or not, as he may prefer. But how about the general practitioner? Provided he wants to do aseptic work, must he also buy such an apparatus, or must he continue to attend his cases according to the antiseptic method? Further: Shall the specialist in operating on minor private cases always carry his sterilizer with him, or take the trouble and sterilize his wrapped-up material at his home? Decidedly not! What we need, and shall certainly have within the nearest future, is the assistance of aseptically well trained and reliable druggists, who keep aseptic surgical material in stock. This point has been specially emphasized by Braatz.[3] There are already a few drug firms here in this city who sell aseptically prepared reliable material. They have aseptic catgut, silk, and silkworm-gut; they have antiseptically prepared drainage-tubes. But, as far as I have seen by personal inspection, they only keep "boiled" aseptic gauze, their cotton is made in factories borated, etc.; gauze sponges cannot be had.

What we doctors have to do is, to induce enterprising druggists, to sterilize the material for doctors as well as patients, according to the newest principles, on the wholesale plan. And the druggists will be almost forced to have reliable "aseptic" material for sale as the doctors will, no doubt, henceforth prescribe less and less "antiseptic" material.[4] The druggist can easily have constructed perforated cylindrical trays, made of tin or glass, which hold about three to five yards of gauze cut and folded, or one-fourth pound of cotton, and can be closed after sterilization by simply turning a second surrounding imperforated capsule. Or the perforated cylinder is put in a second solid tin or glass capsule. The cylinders are sterilized packed with the gauze.

not be boiled in it; if wanted, only a few would be received, and have to be fished later out of the hot water in the dark; instruments would have to boil during the entire act of sterilization, as the small tank containing the water cannot be lifted out and replaced at will; the apparatus also requires timing.

[1] See Meeting of the Surgical Section, of January 8, 1894, MEDICAL RECORD, February 24, 1804, p. 252.

[2] Grundlagen der Aseptik, p. 65.

[1] It will be found in trying my sterilizer that even without spreading the towel on top, the gauze, immediately after sterilization, is not at all moist, but, as it is called, "steam-moist." As soon as it is taken out of the apparatus the rest of the steam evaporates and the gauze is perfectly dry.

[2] Follows demonstration of the author's portable sterilizer. See MEDICAL RECORD, March 3, 1894, p. 285.

[3] Loc. cit.

[4] The only antiseptic gauze which will always remain in use and be useful is iodoform gauze. If ready made, it cannot be sterilized by steam because iodoform is decomposed by the process. In order to do away with the iodoform gauze prepared in factories it will be preferable (in cases where we have to use (tamponade in mouth, nose, rectum, etc.) or want to use material containing this splendid antiseptic) to take steamed gauze and powder iodoform in it, or to sprinkle the steamed gauze with boiled water and rub in the powder with a piece of sterile gauze.

As soon as this is accomplished, asepticism will also be used in minor surgery, and surgical patients who naturally come under the care of the general practitioner can also enjoy the blessings of the new "aseptic era."

A CASE OF BRAIN TUMOR MEDICALLY TREATED.

By CHARLES E. NAMMACK, M.D.,

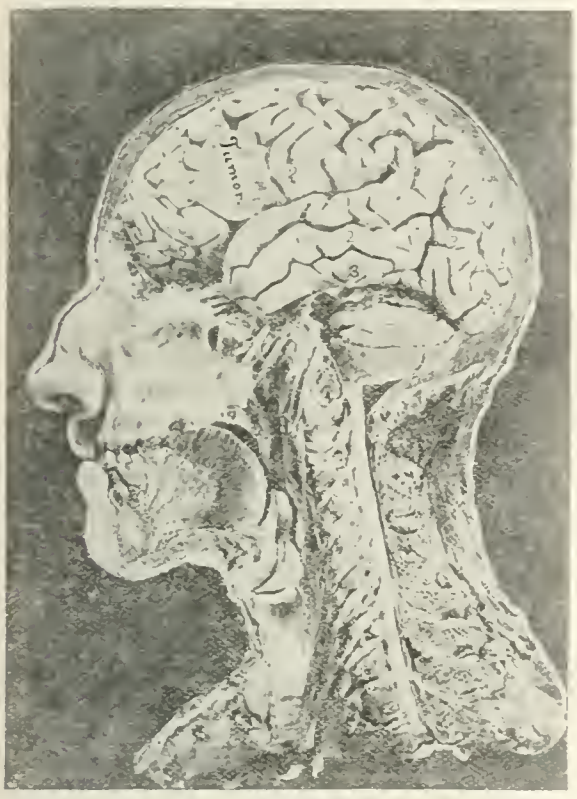
NEW YORK.

ATTENDING PHYSICIAN, NEW YORK HOSPITAL OUT-PATIENT DEPARTMENT; VISITING PHYSICIAN, GOUVERNEUR HOSPITAL.

John L——, butcher, thirty-five years of age, applied, October 12, 1893, for relief from headache which had lasted four months, and had received a variety of treatment. He gave no history of injury, or of alcoholic or other excesses. He was not aware that he ever had syphilis. His business had recently been unprofitable, but this had not given rise to any great worry, as his financial circumstances were easy. Beyond the headache he made no other complaint, except that his bowels were slightly constipated. No vomiting. No vertigo. Slight difficulty in concentrating his thoughts and replying to questions.

Examination: Ophthalmoscope shows double optic neuritis (Dr. Leroy Pope Walker). No tenderness on skull percussion. There is very slight right facial palsy. Patient has a severe paroxysm of pain during examination, and it is noticed that both pupils dilate, right facial palsy is exaggerated, and patient becomes semi-conscious for about ninety seconds, and somewhat dazed afterward for three or four minutes, when pupils resume their original size. No convulsive movements during the attack. Urine is negative, except for excess of phosphates.

Diagnosis is therefore intra-cranial tumor, without symptoms indicative of its exact site. The only feature of the headache was its paroxysmal character. The absence of vomiting was noticeable, but in no wise helpful in diagnosis of localization, or of pathological character of the tumor. Vertigo could hardly be said to exist, the patient merely feeling slightly giddy when suddenly changing from the recumbent to the erect posture. The importance of an ophthalmoscopic examination, unnecessary to emphasize for those habitually engaged with nervous or eye cases, could not receive a more convincing demonstration. There was no diminution of visual acuity, nor limitation of the field of vision, and upon the objective sign (double optic neuritis) alone, in this case, could the diagnosis be made, lead-poisoning and Bright's disease having been excluded by the absence of their characteristic features. To be sure, double papillitis does not make the finding of a tumor post mortem inevitable, but when associated with the other typical general symptoms of cerebral tumor, the cases in which that condition is not found after death are, as remarked by Byrom Bramwell ("Intra-cranial Tumors," p. 40), "fortunately for diagnosis, quite exceptional and rare."



The spasm of the face in this case, coincident with exacerbations of the headache, could hardly be called a localized epileptiform convulsion, although the accompanying dilatation of pupils and purposeless muttering on awaking, together with absence of recollection of any of the events of the paroxysm, bear a strong resemblance to petit-mal seizures. Giving all due weight, however, to this symptom, and considering it to be a limited epileptiform convulsion, it would still be no certain indication of the position of the lesion. The hand grasp was equally powerful on the two sides. Neither anæsthesia nor hyperæsthesia was detected. Neuralgic pains, supra-orbital, infra-orbital, frontal, temporal, and auricular, were prominent symptoms. As already stated, there was at this time neither diminished acuity of vision nor restricted field. Hearing, smell, and taste were not affected. The mental alteration was so slight that patient's wife had not noticed it, until she thoughtfully compared his present with his past mental state. She had attributed his want of former liveliness to the business reverses he had recently undergone. The only derangement of speech was a tardiness in calling the names of objects quickly pointed out to him in succession. General nutrition was well preserved. Appetite good, but bowels sluggish. Temperature was normal, although cranial surface temperature was not tested. Pulse varied considerably from day to day, in frequency as well as in its other characters. Urine was negative, except for the presence of an excess of phosphates. The microscope did not show casts. The left ventricle was not hypertrophied. To the question, Is there an intra-cranial tumor? it was, therefore, comparatively easy to render an affirmative answer. To determine its exact locality or site was more difficult, but a careful review of the symptoms and signs could lead to no other probable conclusion than that the neoplasm involved the centre for the face-muscles and the adjoining motor-speech centre, as indicated by the very slight degree of motor aphasia. In the determination of the pathological nature of the tumor, no assistance could be gleaned from the history, yet since the administration of mercury and iodide of potassium is known to affect sarcomatous, as well as syphilitic, growths favorably, that plan of treatment was decided upon. Patient was given two ounces of blue ointment to be used by inunction, and ten-grain doses of iodide after each meal, to be steadily increased until sixty grains were taken at each dose. The effect of this treatment at first was so happy that the patient became enthusiastic; but the symptoms soon returned with increased violence.

At the suggestion of Dr. George L. Peabody, who saw the case with me after one month's treatment, the iodide was pushed to a daily dosage of four hundred and eighty grains, with marked relief again to the symptoms. Dr. Peabody did not consider the growth to be syphilitic, as the usual clinical features of syphilitic growths (*vide* Bramwell, p. 221) were lacking, yet deemed it proper to exhaust the possibilities of anti-syphilitic medication. After a daily dosage of three hundred grains had been attained, the patient was able for the first time to dispense with the use of an ice helmet. The patient's gratification, however, was not shared by the writer, whose prognosis was, of course, grave, even syphilitic lesions being liable to take on renewed activity after a period of abeyance. Still, since a new hope dawned for the victims of intra-cranial growths on November 25, 1884 (P. C. Knapp, "Intra-cranial Growths," 1891), it was determined to let its rays illumine the gloomy prospect. The patient was accordingly taken to Dr. M. Allen Starr, whose work in this particular field is well known ("Brain Surgery," William Wood & Co., 1893). Dr. Starr agreed with me as to the presence of tumor and its localization in the face-muscle centre (ibid., pp. 4 and 5), but thought it to be subcortical in position rather than cortical (*vide* Seguin and Weir, *American Journal of the Medical Sciences*, August, 1888) and to be gliomatous in nature. In his opinion, the case was a favorable one for operative treatment at once; but the patient could not be convinced of the necessity for this, and he was allowed to continue the iodide of potassium in doses of an ounce daily, the duration of medical treatment to this time having been six weeks. During the next two weeks improvement in the symptoms was so marked that, although the patient had become reconciled to the idea of surgical treatment and was willing to undergo an operation, we could not conscientiously urge it. He was therefore directed to continue the iodide, four hundred and eighty grains per day. Under this treatment, all the subjective symptoms remained quiescent until January 8, 1894, when he had a well-marked spasm affecting the facial muscles, followed by stupor lasting fifteen minutes, but without the severe pain which had formerly accompanied his twitching attacks. At the present writing, patient

has entirely recovered, except as to his choked disks, and it is proposed to reduce the iodide gradually and administer strychnia.

February 9, 1894.

The above report was written February 9, 1894, and on that day the patient was presented by Professor Starr to the class at the College of Physicians and Surgeons. He was entirely free from any symptom, except the defective vision due to his optic neuritis. He remained well there after, visiting his place of business every day and calling at the Out-patient Department tri-weekly until Thursday, March 15th. On this last date he complained of severe headache, and was given phenacetine and codeia. On Saturday, March 17th, his wife called to report that he had attacks of pain, with increasing drowsiness after each

attack. She was advised to bring him to the hospital for operative treatment, and arrangements were made for his admission, but that evening he died. His brain was removed three hours after death and taken to the hospital laboratory for examination. The pathologist, Dr. Frank Ferguson, furnishes the following report:

The specimen shows a neoplasm in the left cerebral hemisphere, involving the posterior third of the third frontal convolution, encroaching upon the lower third of the ascending frontal convolution, and extending down to the tip of the operculum. Its dimensions are $3\frac{1}{2}$ ctm. antero-posteriorly, and $4\frac{1}{2}$ ctm. vertically. It is sarcomatous in nature. From the tumor a cyst extends inwardly through the cerebral substance, beyond the median line, and projects into the right lateral ventricle, the diameter of the projecting portion being $3\frac{1}{2}$ ctm. The cyst-wall at this point is composed of very thin membrane, less than half a millimetre in thickness. On microscopical examination, this wall is found to be composed of spindle-celled sarcoma. The anterior wall of cyst is limited by the knee of the corpus callosum. Its upper wall is limited by the anterior portion of the corpus callosum, which seems to be thinned by pressure.

The tumor itself is 1 ctm. in thickness, and the length of the cyst, from the wall of tumor to the apex projecting into right lateral ventricle, is 8 ctm. The posterior limit of cyst extends to the fissure of Rolando, and must have exerted pressure upon the lower half of the ascending frontal convolution.

29 East Twenty-fourth Street, March 27, 1894.

Progress of Medical Science.

Traumatic Hystero-Neurasthenia. — The condition described by the late lamented Charcot as traumatic hystero-neurasthenia, is reviewed at length in *Médecine moderne*, January 27, 1894, by Dr. A. Schwab, who considers in brief the earlier hypotheses explaining its manifestations, such as the idea that it is due to a meningo-myelitis, to a shaking up of the spinal cord (*commotion médullaire*), or to a diffuse myelitis. Excluding all cases of pure traumatic hysteria, the following are found to be some of the characteristic manifestations of traumatic hystero-neurasthenia. First, there are psychic disturbances, as alteration in the character, in the intellect; trouble with the memory; frequent vertigo, and sometimes fainting; insomnia, and difficulties of speech. Then there are abnormities of sensation, as pain, headache that is almost constant, pain in the spine and sacrum, hyperæsthesia on the injured side, together with anæsthesia to touch, pricking, and temperature. The condition of the reflexes is variable. Sometimes they are exaggerated, sometimes abolished. Muscular sense may be lost. The attitude and gait are often specially characteristic. There is diminution in muscular force, often fibrillary twitchings in the muscles of the face and of the limbs, and paralyses and contractures may be present, similar to those of hysteria. Vision and hearing are both affected. The pupils are dilated and may be unequal. Diplopia, amblyopia, dyschromatopsia, polyopia, are some of the eye-symptoms, together with concentric narrowing of the visual field, the most important of all for diagnostic purposes. The heart and vessels often suffer, as well as the stomach and sexual organs. Tachicardia is not uncommon. General health may be so much impaired as to induce a true cachexia. The course of the disease is extremely variable. Prognosis differs according to the observer. Vibert and Erichsen consider it grave. Judd, Davidson, and Price are more hopeful. Oppenheim takes the darkest possible view. Blum fails to see anything alarming in the situation, finding it necessary to establish beyond doubt the real existence of the patient's symptoms only on account of medico-legal questions that may arise. Simulation and malingering are possible, though rare. The symptoms that can be simulated are psychic troubles, the attitude and gait, neuro muscular asthenia, difficulty of speech, pain, and paralysis. When to these conditions are added concentric retractions of the visual field, cardio-vascular symptoms, fibrillary twitchings, exaggerated reflexes, gastro-intestinal atony, and impairment of general health, all idea of simulation may be instantly rejected.

Elæomyenchysis.—Under this title Dr. J. Leonard Corning has recently described, in the *New York Medical Journal*, a novel method of treating chronic spasm. The essential features of this procedure are the injection into the affected muscles of a non-irritating oil, the point of solidification of which is two or three degrees above that of the normal blood temperature, and the subsequent congelation of the oil in the organ by the external application of cold, either in the form of the ice bag or the ether spray. It is not necessary to continue the application of cold, as the high point of solidification of the oil causes it to remain solid in the tissues for months. As a direct result of the presence of the hardened oil, the blood-flow to the muscle is curtailed, metabolism is interfered with, and the contraction of the organ is mechanically impeded. The author gives the history of an inveterate case of chronic spasm of the splenius, in which all ordinary expedients had failed to afford relief, successfully treated in this way. The method certainly reflects great credit on the ingenuity of its author, and opens a new and promising field in neuro-therapeutics.

The Pecuniary Loss from Phthisis alone, for every million children born, is estimated to be £14,499,40.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, May 12, 1894.

THE INTERNATIONAL SANITARY CONFERENCE OF PARIS.

THE International Sanitary Conference of Paris, which has just closed a two months' session, marks another advance in the progress of State Medicine. This was the seventh similar conference, but the results of its work are to prove far more important than any of its predecessors. While other Conferences have considered questions more immediately relating to cholera in Western Asia and Eastern Europe, this Conference grappled with the more difficult subject of preventing the transportation of the cholera infection from India by the pilgrims to Mecca.

This problem is beset with difficulties from whatever side it is approached. On the one hand are the religious superstitions of the Musselmans that render them intolerant of any control; on the other are the jealousies of local governments, which make them resent any interference with their subjects by other Powers, and, finally, there are innumerable complications arising from European territorial and commercial interests. It appears, however, that the Conference was able to solve all of these perplexing difficulties, and formulate an international series of regulations upon which the states represented will finally be able to unite.

Great credit is due the French Government for its persistent efforts to secure international co-operation in the prevention of the spread of cholera. It called the first Conference as early as 1851, for the purpose of securing a uniform system of quarantine, but the results were not attained. In 1859 it attempted to secure a Conference, but the draft of the convention was not acceded to. In 1866 it succeeded in having a Conference of all the states of Europe, Egypt and Persia, at Constantinople, where many of the questions relating to an international agreement on methods of preventing cholera were discussed. But the time had not arrived for the adoption of the regulations proposed, and the Conference failed of immediate results. But it is apparent that there was a much nearer approach to an agreement than heretofore. Three Conferences have since been held, viz., at Rome, Venice, and Dresden, all of which resulted in agreements as to the methods of dealing with cholera in Europe. Finally, the Government of France called the present Conference, and its programme brought prominently forward the question of an international agreement on regulations governing the pilgrimages to Mecca.

The results arrived at were the adoption of regulations which place the pilgrim under strict sanitary care from his departure to his return home. He must first secure a sanitary passport from the local authority, giving full details as to his person and the locality; at the port of departure he must be detained for cleansing and disinfection; he can embark only on pilgrim ships; these ships must have a qualified physician, ample space, pure water, good food, a disinfecting apparatus, hospital accommodations, etc.; island stations are provided, having every necessary appliance for cleansing and disinfection, where the pilgrims debark and undergo cleansing, as also the ship. At Mecca the pilgrim is under rigid surveillance, and on his return receives another passport stating his condition. The code of regulations is very minute, and if they are enforced in good faith would seem to render it impossible for cholera again to spread from India along the routes of the pilgrimages as heretofore.

We learn that the delegates from the United States endeavored to have the Conference add to its programme the closely allied subject of the prevention of the spread of cholera by emigrants from Europe to the United States. The suggestion was favorably received by the Conference, but as the delegations were selected for the express purpose of considering the pilgrimages of the Musselmans, it was decided to postpone the emigrant question to a future Conference. It is greatly to be regretted that this Conference could not have included the emigrant with the pilgrim, for the larger number of the regulations made for the latter would apply to the former. Every emigrant from Europe to the United States ought to be required to obtain a sanitary passport from the local authority, setting forth the health of the locality and other details as to the cleanliness of his personal effects, freedom from all forms of infection, etc. Without this passport he should not be allowed to embark for this country. At the port of departure he and his baggage should undergo the same cleansing and disinfection, and the emigrant ship should be under similar sanitary supervision. The advantages of such a code of international regulations are twofold, viz., the European States would have a much-needed control of their emigrating classes, and second, our quarantine would no longer be one of detention, but only of medical inspection. We trust our Government will improve the opportunity now offered, and take immediate steps to secure the calling of a Conference of the European states with the United States to establish international regulations governing the movements of emigrants to America.

ITALY'S SERVICE TO MEDICINE.

THE holding of the Eleventh International Congress in Italy naturally draws attention to the obligations which medical science is under to the learned physicians of olden times who flourished in that country. Virchow, in his opening address, took for his subject Morgagni and his work. At the same time Sir Benjamin Ward Richardson publishes in his *Æsclepiad* a very interesting account of Malpighi.

Virchow asserts that the progress of medicine has not been in "epochs," as historians describe it, but that it has rather been a continual growth. This is not quite

the truth, for there cannot be said to have been a continuity or steady progress in development of medical knowledge. Hippocrates first applied the principles of common sense and unbiassed observation to disease, and in this way founded a method and a school. Galen followed with the same inquiring spirit, but added little of actual value to our understanding of the anatomy of man or the nature of disease. For nearly two thousand years medicine was little more than a study of these two masters. Their pupils accepted their teachings, but would not or could not follow their methods. The fact that anatomy was studied seriously at Alexandria, and that the Arabs and Jews developed some brilliant physicians in the East, does not essentially alter the case. It was an Italian, Mondino, of Bologna, who initiated once more a study of anatomy. His most brilliant successor was a Belgian, Vesalius; while a little later it was an Englishman, Harvey, who revolutionized the current views of physiology. But Vesalius was a professor in Padua, and Harvey got his education and his scientific training in the schools of Italy, under Fabricius. Malpighi was the legitimate successor of Harvey, for he completed the latter's work by his discovery of the capillaries. Malpighi was born in 1628, and took his doctor's degree at the age of twenty-five. Three years later he was appointed professor in Bologna. This chair he soon exchanged for one at Pisa, and there his scientific labors began. He saw at once the possibilities that lay in the newly discovered microscope, and his achievements are mainly due to the skill with which he utilized that instrument. Malpighi may be said to be the father of modern histology, though Leuwenhoek shares in a measure the honor. His name has gone down in history associated with the *rete mucosum*, or *rete Malpighii*, and the Malpighian bodies of the kidneys. But he, in addition, gave descriptions which are still classical, of the structure of the spleen, of the liver, the brain, and other organs.

But science is sometimes more indebted to those who originate new fields of work, than to those who simply discover valuable facts, though such facts may, of themselves, arouse new lines of thought and investigation. In Morgagni Italy possessed a man who turned the tide of medical thought into a new and eternally fruitful direction. Up to his time the world did not try to find the seat of disease, for Hippocrates and Galen had already settled this question. Disease lay in the blood. Its humors gave rise to the various morbid phenomena according as bile, phlegm, etc., were in excess. Morgagni was not content with this. He found in some of his autopsies local changes, solidified lungs, inflamed intestines, brains torn with hemorrhages. These things which he saw accounted for the symptoms of sickness much better than any humoral theory. Hence he set for himself the problem of finding out the seat of disease, and putting always the question, *Ubi est morbus?* He consecrated the best part of his life to the study of pathological anatomy, and when ripe in years he produced his great work, "De Sedibus et Causis Morborum"—a work which is still a monument of keen and careful observation, as well as of learning and critical study. Morgagni was eighty years of age when this work first appeared (1761). In these days our scientists do not wait so long. But Morgagni had to begin at the very beginning. From the time of Mondino and his pupils the knowledge of human anatomy has steadily grown, and from that of Morgagni pathological anatomy has also steadily progressed. Having got almost as far as is possible, we are now going back again to the humoralist's stand-point, and are searching for the seat of disease in something behind the *locus morbi*. But the world is not the less indebted to the extraordinary impetus given to science by the old Italian universities.

THE SURGICAL TREATMENT OF CRIME.

A NOTABLE increase of crime has lately been reported, more particularly in the larger cities of our country. The "hard times" have been invoked to account for this social phenomenon. Without wishing to decide whether the pressure of adverse circumstances is alone responsible for the rising wave of criminalism, we are aware that the medical mind loves to speculate on the possibility of repressing crime by other than the purely legal methods now in vogue.

In the *Boston Medical and Surgical Journal* the subject is editorially examined in the light of a recent communication by Dr. Bishop. This thoughtful physician explains his views as follows:

If a case comes into court (the hospital for the care of social maladies being so-called) for treatment for curative or preventive results, and a remedy should be proposed altogether rational and promising, its use is not permitted by the learned judge until a precedent for it has been discovered. Then the counsel in the case turn over the pages of legal lore to the times when people did not seem to know much of their own affairs, and if they find something like the case in hand (like it, because it is not like anything else), then they employ it as a remedy—not otherwise. Under such circumstances it is hardly matter for wonder that the disease keeps ahead of the remedy, or that the law's delay should be a proverb and a threat against honest business. It is not so in medicine. If a physical malady occurs, all scientific methods are at once invoked to discover its nature and an efficient remedy and preventive. Chemistry, microscopy, physiology, are all employed. The profession everywhere is enlisted in the investigation. One doctor is never employed by anybody to defeat the honest efforts of another. Under such conditions it is hardly marvellous that there should occur marvellously contrasting results. In court, in equity cases so called, the chances are largely with the rogue. After some further remarks to develop this idea, Dr. Bishop goes on to say that crime of all kinds is on the increase; our jails and almshouses and other asylums are filled with its products. Lynch-law cases (the signal-lights of lost confidence in courts of justice) are flashing everywhere every day, and every day business transactions are largely based on individual integrity.

On the other hand, it need only be mentioned that the average of human life is being gradually raised. Not only that, however, but all the deadly diseases of the past are under virtual control.

Population is no longer decimated. People no longer fly in insane fear from house and home at the approach of cholera or yellow fever, where medical men hold sway.

Seeing that these things are so, would it not be wise for the one profession to borrow the methods of the other? Nay, would it not be even better to profit by both their example and assistance?

The medical profession have long since shown that criminals are of germ origin, some peculiar character or condition of the spermatozoon resulting inevitably in the production of a criminal. The saying, "*Nascitur non fit*," is as true, therefore, for the criminal as it is for the poet. Now, the doctors have found that the true way to prevent diseases of germ origin is to prevent the germ; and if the law wants to prevent criminals, the sure way to do it is to sterilize the parent criminal, and the only way to do that is to castrate him. Of course there will be a thousand objections urged against the remedy, only two of which will be worth answering. One will be cruelty, the other danger to life, both of which are already negatived by anæsthesia and asepsis. Doubtless there will also be the epithets "uncivilized" and "unchristian" applied to such treatment. But how will prevailing methods of treating criminals compare with this? Now they are penned up together to fester and ferment into more and more repulsive and dangerous criminal forms—the petty thief emerging in form of a daring robber, and the robber in the shape of a murderer.

The practical effect of it all is the production of murderers by cultivation and breeding, and the subsequent slaughtering of them by hanging. The thief, especially a bank thief, is imprisoned until the baby is weaned; but the spots of the leopard change not, and the thief remains a reproducing thief in spite of legal punishment. How simple and how clean and how effectual the germicide method! You destroy the germ factory of the thief, and so reform the thief himself more surely and effectually than all the prayers of the righteous would do it, and prevent the production of thieves. If you do not breed thieves you will not have them.

We owe it to the old English custom of hanging thieves that we are now as well rid of them—more than we owe it to moral suasion.

One curious result of the treatment would be the settling of the race problem.

Castration would hardly be a hardship to the negro. It has been practised upon members of the race from all time. The harem of the Turk is always supplied with negro eunuchs. Why they were selected we may never know. Possibly it was because there were individuals who could be restrained in no other way. Of course a law declaring all crimes not punishable by death shall be punished by castration, would not be tolerated by the Constitution as it is now written. But a law could be enacted punishing all slighter crimes by an exceedingly severe flogging, but releasing the criminal upon producing proof of recent castration. There is a Japanese law which secures the destruction of state offenders by restoring to the family the estate if they could prove that the offender had committed suicide. Truly wonderful is aseptic surgery; it enables us to literally obey the Scripture, which enjoins us to cut off the offending member. It is, of course, taken as understood, that lady criminals are meant also, it being as easy to cure one as the other.

So much for Dr. Bishop, the lengthy quotations from whose essay show conclusively that he entertains advanced views on the subject of criminology. It is not to be expected that the lay press will advocate the practical application of his novel methods. There is too much maudlin sentimentality and hysteria in the newspaper treatment of crime to give any hope of encouragement from that quarter. But the medical press may espouse the author's cause. Taking into consideration the ignominious failure of approved methods to suppress crime, there is no valid reason why "something new" should not be given a fair trial. Our gynecological enthusiasts would doubtless welcome the new departure, as opening up a gleeful vista of wholesale castration. And the testectomist, and epididydectomist would soon claim some share of the triumphant halo at present still monopolized by the youthful oöphorectomist.

THE USE OF HEAT IN OPERATIVE SURGERY.

The successful substitution of heat for antiseptics in the preparation of instruments and surgical dressings has naturally led to the use of heat for sterilizing the wound itself. This is an ancient method. Hippocrates, Oribazius, and later writers down to the time of Paré, were unanimous in recommending the use of the hot iron and boiling oils upon wounds. It may even be questioned if Paré did so great a service, after all, when he substituted for the cautery the use of dirty ligatures.

The systematic and scientific use of heat, however, for rendering wounds aseptic, is a thing of recent date. M. G. Phocas, surgeon to the Hospital Saint-Sauveur, of Lille, has made a particular study of this procedure, more especially in connection with operations for resection. He refers to the experience of Felizet (*Bull. de la Chir.*, 1892) who employed the flame of a gas-jet for making the wound surface aseptic. He describes also the method adopted by Dreesnau, a pupil of Trendelenburg (*Centralb. f. Chirurg.*, 1893, No. 3). This surgeon poured into the cavities of the wound oil brought to a boiling-point by the thermo-cautery. In the same year M. Jeannel, of Toulouse (*Gaz. des Hôpit.*, Nos. 59 and 62), proposed to make the surfaces aseptic by touching them with boiling water.

In 1892 M. Phocas began to employ boiling oil according to the method of Trendelenburg. At the same time he undertook, with the help of his assistant, M. Hennecart, some experiments to determine how much heat the living arteries and nerves could bear without disintegration. Three different methods of using heat were tested: first, cold oil was poured into the wound and then raised to a boiling-point by a thermo-cautery; second, boiling oil; and third, boiling water applied directly.

It is sufficient to say that the experiments showed boiling water to be much less injurious to the tissues than the oil. M. Phocas finally adopted the following procedure: In osseous cavities he poured in cold oil and heated it with a thermo-cautery for three or four seconds. In other wounds, but more especially in resections and arthrectomies, he touches the wound with plugs of absorbent cotton upon which he has poured water just at the boiling-point. In this way every part of the wound is reached by water at a temperature of about 80° C. Each part is touched for three or four seconds, and the procedure is repeated several times.

M. Phocas states that since he has used the boiling water his results have been "incomparably better" than they used to be.

A Bill Providing for Registration of Physicians in Massachusetts has passed the Senate.

VACCINATION AND THE LAW.

Our Boards of Health are sometimes compelled to act autocratically and to strain the law a little in order to protect the public. We have feared that they would get into trouble some day, and in Brooklyn this expectation was recently realized. Two expressmen who refused to be vaccinated were quarantined in their stables. Their counsel obtained a writ of habeas corpus, and challenged the right of the authorities to keep them in quarantine.

They were brought before Judge Gaynor, who said that he did not see the shadow of right in the action of the Health Commissioner in imprisoning the men. "It is beyond anything I ever thought of," he continued, "that such an officer should have the power to impose perpetual imprisonment in this way. The discretion you claim is limitless, and on the same theory yon might as easily sentence a man to death as to perpetual imprisonment. I am of the opinion that you have no such power."

The position of the judge is undoubtedly right. The Health Boards have no power in this State to compel vaccination directly, and to punish by imprisonment those who will not be vaccinated. We doubt if a law compelling universal vaccination could be enacted at the present time.

The people have been so long freed from the dangers of small-pox through vaccination and quarantine, that the disease does not awaken apprehension as formerly. Therefore they will not tolerate any radical measures without some further object lesson of epidemic character. We hope and believe that such object lesson will not be furnished. Nearly all American children are vaccinated, and the majority of adults are sensible enough to look after themselves and families.

News of the Week.

The New Post-Graduate Medical School.—The formal opening and dedication of the new Post Graduate Medical School building took place, May 8th, with a reception and appropriate services in the afternoon, and addresses in the evening by Dr. D. B. St. John Roosa, the Rev. William R. Huntington, and Mr. St. Clair McKelway. A report was read by Dr. C. C. Rice, giving the following history of the origin and development of this medical school, a chartered institution of learning that demonstrates by its success the effective force of enthusiasm and unselfish effort in a common cause :—

The idea of clinical medical instruction for graduated physicians assumed tangible form in 1882, when the Post-Graduate began its existence in the old College of Pharmacy on Twenty third Street. Dr. D. B. St. John Roosa, Dr. William A. Hammond, Dr. Little, and Drs. Pallen, Piffard, and Sturgis were its founders. The first year there were one hundred students; last year there were over five hundred. All teaching has been by actual demonstration of patients, didactic lecturing having no part in the methods of instruction. The hospital was added to the school after its removal to the Twentieth Street building in 1885. Each department of medicine and surgery is taught by men who have attained a special reputation in their departments; in other words, by specialists, numbering two hundred.

The mission of the Post-Graduate is to elevate the standard of medical education, giving equal advantages to men and women. The results of such instruction in a teaching hospital are widespread and make themselves felt throughout the country. Skilful physicians and surgeons are not alone to be found in the great cities, but in the smallest villages as well. Students come from Canada, the West Indies, and from every nook and corner of the United States. The new Post-Graduate is necessarily a large building became its needs are so great. Below the executive and school floor there are two others—the dispensary, on a level with the street, and below it workshops for the manufacture of special apparatus, and rooms for certain kinds of surgical work. There are three teaching amphitheatres, libraries, reading-rooms, laboratories, the babies' wards, a female ward, an orthopædic ward, a male ward, and a nervous ward. At present there are ample accommodations for two hundred patients. The ambition of the Post-Graduate School is that it shall become the best-equipped teaching organization of its kind in the world. The ideal institution is a school with both ample space for out-door patients and for large hospital accommodations under the same roof, the hospital being so generously supported by the public that its beds are free to the sick poor. The best instruction cannot be given if interesting and difficult cases in surgery are turned from the door because they are unable to pay board. The school enjoys a legitimate income through its business of teaching. The fees of the students defray current expenses. No salaries whatever are paid to the teachers of the Post-Graduate. They are willing to do the work gratuitously, and only ask that the public help to endow the beds and complete the building fund. And there is every reason to have confidence in the mind of the metropolis, so quick to appreciate effort directed along the lines of higher professional education and relief of suffering and indigent humanity. Once acquainted with the purpose and scope of the Post-Graduate Medical School, its educational value and practical work, the New York public will help place the entire institution on a financial basis that will enable the directors to carry out the purpose for which it was created.

Bellevue Hospital Alumni Association.—The Bellevue Hospital Alumni Association gave its annual dinner at the Windsor Hotel, New York, Tuesday evening, May 1st. Dr. W. H. Katzenbach, President of the Association, acted as toast-master. The following gentlemen responded on call: Professor A. A. Smith, Professor F. S. Dennis, Dr. T. H. Burchard, Dr. L. Carter Gray, Dr. F. P. Foster, Professor E. B. Deuch, Dr. A. H. Doty, Professor A. Flint, Jr., Dr. W. H. Westerfield, Class '94.

The Transactions of the Pan-American Medical Congress.—The proceedings of the First Pan-American Medical Congress were compiled by the Secretary-General, Dr. Charles A. L. Reed, and transmitted to the Department of State in November, 1893. By recent joint resolution of the Senate and House of Representatives the manuscript was transmitted to Congress, and a concurrent resolution has been adopted directing the public printer to print the same. The manuscript is now in the office of

the public printer, and will be put to press at once under the supervision of the editorial committee, of which Professor John Guiteras, of Philadelphia, is chairman.

Credit to Whom Credit is Due.—At the nineteenth annual meeting of the United States Hay-fever Association, Dr. S. S. Bishop, of Chicago, obtained the prize for the best essay on the subject of hay fever, proposing the theory of uric-acid origin, with salicylate of soda for treatment. One year previous to the reading of the essay, Dr. Shawe Tyrrel, of Toronto, read a paper before the Ontario Medical Society, entitled "A Predisposing Cause of Hay Fever," which was afterward published in the Canadian journals, setting forth the uric-acid origin of the affection, and its treatment by soda salicylate and a proper diet.

Report of Health Department on Laryngeal Diphtheria.—The following report has been sent to Hon. Charles G. Wilson, President of the Health Department of New York:

"SIR: Some months ago I had the honor to present a communication to the Board of Health, directing attention to the results obtained in the bacteriological examination of a considerable number of cases of so-called membranous croup. In that communication it was shown that, in a large proportion of these cases, bacteriological examination disclosed the presence of the Klebs-Loeffler bacillus of diphtheria, proving that these were really cases of true diphtheria of the larynx. It was further shown, by the investigation of the clinical histories of these cases, that in many instances there was satisfactory proof that they were cases of diphtheria in which previous and subsequent infection could be traced. Since the former report a large number of further observations have been made, which, I believe, justify this department in considering so-called membranous croup as laryngeal diphtheria.

"Two hundred and eighty-six cases of so-called membranous croup in children have been examined bacteriologically. In 229 of these cases the characteristic Loeffler (diphtheria) bacilli were found, and these cases were thus proven to be true diphtheria. Of these 229 cases 167 showed no pseudo membrane or exudate above the larynx, while in the remaining 62, although the larynx was mainly involved, there was also some pseudo-membrane present on the tonsils or in the pharynx. Of the 57 cases examined in which no Loeffler bacilli were found, in 17 the cultures were unsatisfactory, leaving the bacteriological diagnosis in these cases doubtful. Of the 40 cases remaining in which no Loeffler bacilli were found, in 27 the disease was confined to the larynx or bronchi, and in 13 there was also more or less exudate or pseudo-membrane present on the tonsils or in the pharynx.

"It has been shown, therefore, by these examinations, that about eighty per cent. of the cases of so-called membranous croup in children, which have been subjected to bacteriological examination in the laboratory of the Health Department during the past ten months, were cases of true diphtheria; and of the remaining twenty per cent., six per cent. were doubtful, and only fourteen per cent. were undoubtedly not diphtheria. Further investigations have also shown that cases of pharyngeal diphtheria frequently precede, or follow, these cases of croup.

"Inasmuch, therefore, as so-called membranous croup has been clinically separated from diphtheria, and as cases of this disease are not usually considered as laryngeal diphtheria, and are not reported to the Department as diphtheria, I would respectfully recommend that so-called membranous croup be regarded as pharyngeal diphtheria, and be included in the list of contagious diseases concerning which reports are required from physicians of this city.

"Respectfully submitted,

"HERMANN M. BIGGS,

"Pathologist and Director of the Bacteriological Laboratory."

New Doctors.—The fifth annual Commencement of the Michigan College of Medicine was held in Detroit, Thursday afternoon, March 29th. The graduating class numbered twenty-seven. The Keokuk Medical College graduated a class of thirty-seven on March 6th. The same evening the College of Physicians and Surgeons of Keokuk graduated a class of twenty.

Portland, Ore., has two medical colleges, which recently held Commencements and graduated classes of five and six, respectively. At this distance it seems as if it would be better if Portland had one medical college and a class of eleven.

The Kansas Medical College proposes to have a new building.

The City Health Board has found and condemned tuberculous meat in the New York markets three times in the past week.

Fighting Vaccination.—Suits to prevent the enforcement of school vaccination orders are growing in frequency. In addition to those already reported in New York, Pennsylvania, Indiana, and Illinois, similar proceedings have been begun in Connecticut at New Britain, and at Beloit in Wisconsin. At the latter place the State Board of Health is defending the School Board, and will probably be called upon to do the same for other boards in that State.

Dr. M. L. James, of Richmond, Va., has retired from the Professorship of Practice of Medicine of the Medical College of Virginia.

Death of Dr. Keating, U. S. A.—Dr. William V. Keating died suddenly, on April 18th, in this city, aged seventy-one. He was graduated from the University of Pennsylvania in 1844, and in 1861 was elected Professor of Obstetrics in Jefferson Medical College, holding the latter position for but a short time. From 1862 to 1865 he was Medical Director of the United States Army Hospital at Broad and Cherry Streets. He was the Medical Director of St. Agnes's, St. Mary's, and St. Joseph's Hospitals, and a member of numerous medical and scientific societies. He was the American editor of Ramsbotham's "Midwifery" and Churchhill's "Diseases of Women."

The Wistar Institute of Anatomy of the University of Pennsylvania will be opened with appropriate ceremonies on May 22d, when an address will be delivered by Dr. William Osler, formerly Professor of Clinical Medicine in the University and now Chief of the Medical Department of Johns Hopkins University. Dr. Harrison Allen has been made Director of the Institute, and Dr. Milton J. Greenman, Assistant Director.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 19, 1894.

D. B. St. John Roosa, M.D., President, in the Chair.

Amendments to the By-laws.—At the recommendation of the Committee on Library, amendments to the by-laws were adopted, granting members the privilege of taking books from the library under certain restrictions.

Bureau of Nurses.—Dr. Gray, chairman of the Bureau of Nurses, reported that since the bureau had been organized, in January, two hundred and seventy-five nurses had registered, there had been fifty-four calls, the income had been over five hundred dollars, or above the expenses since the bureau had been established. A number of communications had been received, suggesting that there should be no charge to the public on engaging a nurse from the bureau, but such a proposition seemed too absurd to require serious answer. The Academy had discharged more than its duty to the public when it vouched for the character and ability of the nurse. A pay telephone would soon be provided. Physicians should on each occasion come to the bureau for the nurse, instead of going directly to the nurse, if they would assure the success of the undertaking.

Portrait of the Late Laurence Johnson, M.D.—Dr. F. A. Castle, on behalf of the Council, presented a portrait of Dr. Laurence Johnson, which had been donated by certain members. Dr. Castle's portrayal of Dr. Johnson's character and life-work constituted a just and warm tribute to the memory of the deceased. Marbout's painting representing Ambrose Paré using the ligature for the first time to arrest hemorrhage, presented by Fellows of the Academy, had been accepted by the Council.

Persistent Albuminuria and Glycosuria in Functional Nervous Disease, and their Significance.—Dr. Landon Carter Gray then read a paper upon "Persistent Albuminuria and Glycosuria, with Frequent Hyaline Casts, in Cases of Functional Nervous Disease." He first gave the results of his examinations in sixty-nine cases, which were to show that in most of the cases there was persistent slight, or more than slight, albuminuria and glycosuria, and frequently hyaline casts. He reached the following conclusions: 1. That many functional nervous diseases, especially neurasthenia, can constantly, or well nigh constantly, be accompanied by albuminuria, excess of uric acid, and oxalate of lime, and occasionally by excess of urea, indican, and hyaline casts. 2 It is probable that these urinary products are results, rather than causes, of disease. 3. That these conditions very probably represent what has been called lithæmia. 4 That it is probable that many, if not most, of these cases are not cases of early nephritis. 5. That it is possible that there are different albumins in the urine, and that upon the determination of these will rest the future diagnosis of nephritis from other diseases. He then passed on to the treatment of the various forms of these cases, showing that in his experience diet had been of little use, and that relief of the existing form of nervous disease brought, *per se*, relief of the albuminuria and glycosuria.

A Precursor of Arterial Fibrosis.—Dr. Alfred L. Loomis was of opinion that persistent albumin in the urine, however slight in amount, always indicated an abnormality of some kind. That abnormality might not be found in the kidneys, but there was present variations in blood pressure, or faulty use and elimination of the materials taken into the body. Temporary albuminuria existed under various circumstances independent of organic or serious lesions, but persistent albuminuria denoted, in his opinion, something seriously wrong with the subject. The records given by Dr. Gray would seem to show that albumin was constant in the urine of some cases of nervous disease, and when one reflected on its significance it appeared that there must either be something abnormal in the condition of the blood or in the vascular pressure. He thought the author might modify his statement, that there was absence of high arterial tension, if he would examine the patient at all hours of the day, for not infrequently persons who showed no increased tension during the waking hours, did so at night. But neurasthenic patients were apt to be feeble, and there need not be high arterial tension to account for the slight albumin and sugar in the urine on the basis of faulty circulatory state. Every epileptic, so far as he knew, had albumin in the urine, and it was due to change of blood pressure attending the nervous phenomena. Regarding lithæmia, it was not necessary that the urine contain a large amount of uric acid in order that the nervous phenomena of this condition should become manifest. Back of it was faulty metabolism which, continued long enough, led to arterial fibrosis. A man might go on ten or fifteen years taking little exercise, eating more than he should, using stimulants of some kind, and at the end of that time show well marked cardiac and arterial fibrosis of gradual development. Before the evidences of high arterial tension, of cardiac hypertrophy, of hardened arteries—signs of the advanced stage of arterial fibrosis—there had been a variation in the blood-pressure within the kidneys which permitted albumin to escape. The future of a man living in a certain way, having constant slight albuminuria, could be predicted with nearly the certainty of the rising sun. Dr. Loomis said he had yet to examine the urine of a man sixty years of age which did not contain some hyaline casts. It was one of the attendants of the arterial change of old age, of persons who had started on the downhill of life's pathway, which always led to general fibrosis, to infirmity, and the grave. In the speaker's opinion, Heller's nitric-acid test was sufficiently delicate for determining the presence of albumin.

Dr Andrew H. Smith said: I have had several cases recently similar in every particular to those described by Dr. Gray. Within the past few weeks two gentlemen, both of them having enormous financial interests which they have been watching with intense solicitude during many months, have come to me complaining of symptoms indicating nervous exhaustion. In each case I have found, or rather an expert in urinary analysis has found, a trace of albumin, a trace of sugar, an excess of uric acid, more calcium oxalate than there should be, a little too much indican, and a few hyaline casts. One of these patients presented these conditions two years ago, and his urine has improved rather than otherwise since then.

Now, as to the question of the significance of slight albuminuria, I think it is all important that we should recognize as a fact that there is no definite substance to which the name albumin is attached. The name is given arbitrarily to any substance which will respond to certain arbitrary tests. But no two specimens responding to these tests will correspond exactly with each other when subjected to quantitative analysis. We have exact chemical formulæ for starch, sugar, cholesterin, hæmatin, and all crystallizable and some uncrystallizable organic bodies; but when we come to albumin, globulin, mucin, and all the other various albuminoids, the chemists are at fault. They cannot tell us just how many atoms of each of the component elements go to make up the body in question; in other words, they cannot give us definite chemical formulæ to express their composition.

Now, I consider albumin as simply representing an indefinite stage in a process of change from the inorganic food-elements, as they come from the earth and the atmosphere into the organized vegetable or animal tissues. Albumin is always the product of vital activity. It is never formed in dead matter. No conceivable chemical reaction can produce it apart from vital energy. It is a stage, not a step, in a constructive process. Material that was not albumin gradually becomes albumin, and then gradually passes on to finally become tissue. But while it is albumin it is all the while changing, and it is

as hard to tell just when it gets to be albumoid as to tell just when night passes into day; and it is as hard to tell just when it passes into the next stage of development as to decide just when day has given place to night.

Now, I think it can be shown that, somewhere along this line of change, material that either is going to be, or has been, albumin, has the right of way, so to speak, into the normal urine. If you agitate normal urine very thoroughly with one-third its bulk of ether, a gelatinous substance will slowly rise to the surface, and may form a plug so dense that you can reverse the tube without spilling its contents. Now, this is an albumoid substance, but it is not albumin; that is to say, it will not respond to the tests which it has been arbitrarily decided that a substance must respond to in order to be called albumin. The change has not gone far enough yet, or perhaps it has gone too far. But as there is no definite boundary line, and that which is not albumin shades off imperceptibly into that which is, and as in the blood-serum all these shades are blended together, we can see how easily some material may pass into the urine that will respond to some of the tests for albumin. In both the cases of which I have just spoken heat and nitric acid gave no reaction. The albumin was not in that stage of development. But Millard's test showed a faint trace, because Millard's test is adapted to another stage.

Now, clinically we know that albumin in the stage of development that responds to heat and nitric acid is a very ugly constituent of the urine. On the other hand, the substance which is separated by ether is harmless. May it not be also that a less ominous prognostic significance attaches to the presence of the substance revealed by Millard's test? Indeed, may not the particular test employed in a given case be an important factor in the prognosis? May we not find that the material that responds to one test is comparatively innocent, while that which corresponds to another test is associated with grave organic disease. For my own part I am unwilling to consider a case as certainly one of nephritis, so long as the urine gives no precipitate with heat and nitric acid, even though Tanret's or Millard's test may show a trace of so-called albumin.

Another point—in nearly all these cases there are present crystals of oxalate of lime. These crystals are angular and excessively hard, and it may well be that they irritate mechanically the delicate lining of the tubes, and thus give rise to albumous exudation, traumatic in its origin. I have several times seen the slight traces of albumin disappear with the disappearance of the oxalate.

Opposite Experience.—Dr. Christian A. Herter said the results of his observations did not correspond with those of the author in certain regards. During the past two years he had examined the urine, for various products, of about two hundred persons, most of them suffering from some form of nervous disease, and in only two did he find albumin in the urine, sugar in only one. In speaking of albumin he thought we should include only serum albumin, although it seemed Dr. Gray had not made this distinction. If albumin could not be found by the cold nitric-acid or the picric-acid test, he thought we should assume that it was not present. He had found uric acid increased in most neurasthenic cases, but did not regard it as an indication of disease unless much increased and for a long time. He was disposed to accept the view of a German observer, that excess of uric acid was due to excessive breaking down of nuclein from the nuclei of cells. As to indican, it was never dependent upon metabolism, but upon putrefaction of proteid substances in the intestine. Life-insurance men had told him that albumin existing in the urine a long time developed fibroid kidney.

Dr. Gray said, in closing, that while he might be willing to believe persistent small amount of albumin in the urine would in time lead to arterial fibrosis and cardiac hypertrophy, yet it had not done so in any cases which had remained under his observation. No case had developed into indubitable renal disease. Millard's test for albumin was much more sensitive than the nitric-acid test. With it he had repeatedly discovered albumin where the acid test had failed. He could not understand why Dr. Herter should regard serum albumin as the only albumin.

Registration of Births.—Dr. Alexander Hadden called attention to a bill before the legislature relating to the registration of births. As it was an absurd measure, being no improvement upon the existing law, he hoped the Academy would do something to prevent its passage and to bring about legislation which would make the registration of births of value as evidence in courts of law. A committee of three was appointed to report at the next meeting—Drs. Hadden, Armstrong, and Roosevelt.

SECTION ON SURGERY.

Stated Meeting, March 12, 1894.

Charles A. Powers, M.D., Chairman.

Epithelioma of Forehead and Orbit; Flap from Thigh.—Dr. Carl Beck presented a woman, fifty-six years of age, good family history, who when he saw her, about four months ago, had an ulcerating sore above both orbits about the size of his hand. The pathologist pronounced it an epithelioma. He decided to cover the space by the dry-flap method. The granulations were scraped away, the parts were washed with a solution of bichloride, followed by salt solution. From this point on he worked with dry instruments and dry hands, took a flap from the thigh five by three inches, including only the cutis and dermis, no fat; bleeding had ceased, the flap was put on the wound immediately, no sutures used, no pressure beyond what was necessary to hold it in place. At the second dressing, two weeks after the operation, the flap had united thoroughly, there being no gangrene even at the margins. But five weeks after the operation destruction by the disease had set in, and at present only a small area of the transplanted skin remained. The conjunctivæ were involved, but sight was still good. The patient was more cachectic, and further interference would hardly be justified because of her low condition.

Dry Flap to Injured Finger.—Dr. Beck also presented a boy whose entire little finger had been denuded by a stone falling upon it, so that his first thought was to amputate it; but he concluded to apply a skin flap from the thigh, in the manner just described. Only one-third of the flap was found united after a week. A second flap was applied, this time with entire success. The difference in technique was that, at the first operation some pressure was applied over the transplanted flap, none at the second.

Dr. Erdmann said he had had several cases in which he had transplanted flaps in this manner, from two to five inches in diameter, and all had taken nicely. He used no pressure.

Considerations on Different Types of Surgical Inflammation, Based on Bacteriological Examinations in over One Hundred and Twenty-five Cases.—Dr. C. N. Dowd read the paper. All surgeons, he said, had noticed differences in the types of inflammation which came under their care. Some types were rapidly fatal; others pursued a slow course; some tended to spread, others remained limited; some subsided under mild treatment, others resisted even heroic measures.

At the Vanderbilt Clinic, the New York Cancer Hospital, and elsewhere, he had succeeded in making bacteriological cultures from wounds in about one hundred and forty cases, representing various types of inflammation—cases of acute spreading inflammation, of local inflammation, of granulating wounds, of abscesses, of furuncles, of sebaceous cysts, of stitch-hole and needle-wounds, etc. Dr. Park had done nearly one half the bacteriological work. The result had been that different types of inflammation had been found to correspond pretty regularly with certain kinds of bacteria. First, all cases in which there was acute inflammation with consti-

tutional symptoms gave streptococci or golden staphylococci; second, inflammation of less severe type, sometimes with limited suppuration of the hand or foot, sometimes with a little moisture, gave the white staphylococcus or a lemon colored staphylococcus closely allied to the white. Then there was a class in which no bacteria, or indifferent ones, were found, as in cold abscesses, buboes, or healing ulcers; and still another class of mixed type of inflammation and different bacteria. Where the golden staphylococcus was found in the original wound and metastatic abscess had formed, the streptococcus was found to be the cause of the latter

Then there were cases on the border line between acute cellulitis and erysipelas, and in them streptococci were found. The weight of bacteriological authority was also in favor of the view that the differences between streptococci and the germs of erysipelas were not greater than was frequently seen in individuals of the same species.

This was a matter of much practical importance, since it showed the necessity for guarding simple wounds against contamination with streptococci, lest it lead not only to a more severe type of simple acute inflammation, but possibly to erysipelas.

There were many other cases in which streptococci were present, yet which did not show tendency to spread. Whether the milder course of the disease was due to the general condition of the patient, a difference in the kind of streptococcus, or to the manner in which it had in the first place gained a foothold, was not known. The same difference in behavior had also been observed in relation to other bacteria.

The staphylococcus pyogenes aureus was found in pure culture twenty seven times, but in no case in which it alone was present was there a spreading inflammation. The furuncle represented a form of inflammation in which the staphylococcus might be the cause and be attended by severe inflammation, necrosis, and constitutional symptoms, but it did not spread by direct extension as did streptococcus inflammation.

The white staphylococcus was found in pure culture eleven times, only one being a case of cellulitis. It was very evident that this was a type of inflammation far less severe than the types caused by the streptococcus and the staphylococcus aureus, and a type which did not call for the same treatment. White staphylococci were regularly found in superficial granulating wounds, in conjunction with other bacteria. A mass of evidence indicated that this germ ordinarily possessed little virulence for man, although it was not denied that it might show virulence. Its general mildness was a fact of importance since it was present on the skin and even in what we called aseptic wounds. A lemon-colored staphylococcus was observed in five cases, but was probably the white form in a culture kept longer than usual—eleven days.

Seventeen times no cultures, or few, were found, usually in sinuses with pus-like appearing secretion, or tubercular abscesses, sebaceous cysts, necrosed bone, bubo. The pus without bacteria, or but few, which continued to be discharged from bone abscesses, possessed little virulence, and in such cases healing could be readily induced by blood-clot, as it could not where streptococci or staphylococci were found. If we could distinguish between cases belonging to this mild form of inflammation and those of the severe form, we could cure them much more quickly by suture or the blood-clot method than by leaving them to heal by granulation.

The fourth type included cases in which the bacteria of decomposition apparently were the cause of keeping up an inflammation originally started by another source of infection.

Dr. Park opened the discussion. In cases of mixed infection one had to use care, else he would find the staphylococci alone and overlook streptococci. He felt sure that such an error would account for a number of cases having been reported in literature as due to the staphylococci, when streptococci must also have been present to account for the severity of the symptoms. Regarding divisions of streptococci according to whether they grew in long or short chains, etc., it had no bearing upon their virulence. Even virulent streptococci lost their virulence after a few cultures. It was an interesting fact that streptococci caused a spreading inflammation; staphylococci, a local one. When both were present, the staphylococci would be found to remain in the original abscess; the streptococci, to spread. This was of practical value, as it showed the importance of guarding a wound against infection by a new and more virulent micro-organism. Dr. Park referred to his investigations reported before, in which he found streptococci in all throats, although many had little virulence, while others had considerable.

Dr. W. B. Coley referred to the observations of two authors which had led them to divide streptococci into two classes: one producing results like those described by Dr. Dowd; the other called septicæmic streptococci, which, when they entered through minor wounds and eruptions might go on to cause fatal septicæmia before the formation of pus. Personally, Dr. Coley was disposed to regard the micro-organisms which caused erysipelas as distinct from the streptococci under discussion.

Dr. George P. Biggs related a case of very small ulcer over the tibia, rapid spreading, very superficial gangrene extending to the groin, delirium, constitutional symptoms of infection from streptococci, death. Pure cultures of streptococci were found before and after death. There was but one spot of pus, the size only of a pin-head, and this contained streptococci in abundance. He regarded streptococci inflammations as far more virulent than those due to staphylococci, and the latter were, as a rule, local.

Dr. W. W. Van Arsdale was glad to see bacteriologists giving attention to surgical matters. It would be a good thing if, by examination for micro-organisms, the surgeon could tell the nature of the case of inflammation under his care, its severity, and the treatment appropriate under the circumstances. Unfortunately, however, in some instances the germs might kill the patient before the bacteriologist had made his cultures. Clinical experience must lead one to accept Dr. Dowd's conclusions, that there was a difference in the character of inflammation in different cases, and one was not surprised to learn that it corresponded to differences in the character of the micro-organisms present. After hearing the paper one would not think of opening a tubercular abscess in such a way as to expose it to infection with streptococci. Some light might be thrown on mixed infections by the observation that streptococci, cultivated on pure pus which had been sterilized, developed and became more virulent, while staphylococci were destroyed by it in a few days. Anthrax bacilli seemed also to be killed by the pus, which would seem to show that the best way to treat anthrax pustules might be to let them alone, for if incisions were made they might be rendered more virulent. Also simple cases of furuncle, such as were at times seen on the face, might also be let alone, since by incision one was liable to infect them with more virulent micro organisms than the staphylococcus present, and not only delay the cure, but cause extensive inflammation and abscesses

The Chairman, Dr. Powers, mentioned a case similar to the one of Dr. Biggs, in which violent and fatal septicæmia followed an operation on the tongue for cancer, although very little pus formed. In view of Dr. Park's remarks regarding the presence of the streptococcus in the mouth at all times, it pointed to the necessity for special care in disinfection before operating. If in a given wound the streptococcus was found, it would lead the surgeon to make a more guarded prognosis. Some furuncles were also quite malignant and called for radical treatment, but it was not to this class that Dr. Van Arsdale had referred.

Some further remarks were made by Drs. Morris, Gibson, and Dowd.

Inoperable Sarcoma of the Ilium.—Dr. F. Kammerer

showed a young man, from Dr. Shrady's service at St. Francis Hospital, who had an immense sarcoma of the right ilium, the growth having reached the inoperable stage before being seen by the surgeon. Dr. Coley was asked whether inoculations with the toxic principles of erysipelas would give any prospects of benefit in such a case. Dr. Coley referred to two cases in which it had reduced the tumors.

Practical and Efficient Sterilization of Materials for Private Operations.—Dr. Willy Meyer, by request of the Chairman, exhibited his apparatus for sterilizing instruments, towels, and other materials at the patient's house.

Mr. Van Dusen also exhibited a sterilizer. Dr. Stewart described his, which was composed of a series of trays, one above the other; and Dr. Walker exhibited sterilized catgut in a series of bottles contained within a glass case, kept for sale by Druggist Van Horn. The opinion was expressed that it was time druggists should keep sterilized material ready for use by the surgeon.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, March 29, 1894.

Malcolm McLean, M.D., Chairman.

Instruments for Anterior Vaginal Fixation.—Dr. Vineberg presented two instruments which he described in connection with some written remarks upon the indications for anterior vaginal fixation of the uterus; an operation which he had performed nine times, his first operation having been among the first done in this country. The knife shown had a strongly convex blade. The second instrument was a long uterine sound, rather large shank, with a bulb on the end to avoid danger of perforating the uterine walls.

Needle.—Dr. H. T. Hanks exhibited a needle to take the place of the full-curve needle which went with the Hagedorn needle-holder, the objection to the latter needle being that it could not be used with ordinary needle-holders. The needle presented, instead of being a full curve, presented two ends which formed an obtuse angle with the central portion, and could be grasped by the American or other needle holder.

Trocar.—Dr. Hanks also exhibited a trocar and cannula, which had a special use as well as the ordinary one. When, for any reason after abdominal section, it was desired to drain through the vagina, a cannula with a funnel opening could be pressed against the vaginal vault and the trocar plunged into it from above. The perforated cannula on the trocar could then be passed down and irrigation made, after which, as a drain for the required time, a strip of gauze could be passed down through the cannula, and the latter removed. The gauze was subsequently withdrawn a short distance at a time, and finally altogether.

Dr. Mundé said he had not yet found a needle holder which would both hold the needle and not break it. In vaginal drainage he preferred a flexible rubber tube.

The Chairman, Dr. McLean, said he was in the habit of tempering his needles before using them, so that they would not break when clasped by a reliable needle-holder. He held the needle in the flame of an alcohol lamp, then plunged it into wax, which made it tough and did not impair its usefulness.

Abscess of the Ovary.—Dr. Paul F. Mundé read the paper. Only since the progress made by abdominal surgery during the past fifteen years had abscess of the ovary come to be recognized as not an uncommon condition. Puerperal abscess of the ovary, however, had been mentioned in the older text-books. and was recognized as a very dangerous condition, usually ending in death of the patient. While the author was unable to say just how frequently abscess of the ovary occurred, yet it could be inferred that it was not very rare when he stated that he had operated upon sixteen cases. Out of the sixteen women only five had borne children or aborted, so that it was not so often connected with the puerperal condition. The reason it was formerly regarded as puerperal abscess of the ovary, doubtless was the fact that the condition went unrecognized until some accident connected with the puerperal state brought it to light. When one recalled the highly vascularized condition of the ovary, its physiological changes, and exposure to trauma, it could be readily understood why this organ might sometimes become the seat of inflammatory action and abscess.

In the sixteen cases in which he had found abscess of the ovary he did not include those in which this condition complicated pyosalpinx. There was, it was true, thickening of the walls of the Fallopian tubes, a chronic inflammatory state, but not pyosalpinx, which meant pus in some quantity. Women having abscess of the ovary might not be seriously ill; they might be able to be about, but they were scarcely ever altogether free from pain, and pain was increased on exertion and at the menstrual flow. At times there might be chills, moderate rise of temperature, and in acute cases, as in the puerperal condition, the symptoms became much more aggravated and active surgical interference was called for, as perforation was imminent. In the less acute cases the patients were more or less chronic invalids, systemic infection not being striking because, usually, the abscess was hemmed in by adhesions arising from successive attacks of inflammation and matting together of adjacent structures. The absorbent powers of the walls of such an abscess were slight, their thickness prevented rupture, and the patients continued to live often for months and years in a state of more or less aggravated invalidism.

Diagnosis.—For some years past attention had been centred upon the tubes in cases of a fluctuating tumor felt in the pelvis, and while Dr. Mundé did not deny that pyosalpinx was much more common than abscess of the ovary, yet he believed the latter condition had sometimes been mistaken for the former because physicians had not learned to differentiate between the two. When abscess of the ovary existed one felt a rounded tumor, similar in shape to an orange, whereas distention of the tube presented an elongated tumor, and combination of abscess of the ovary with pus-tube gave a tumor of irregular outline, the tube being curled back and attached to the ovary. In the combined disease of tube and ovary, however, differential diagnosis was not always possible, but this was unimportant since pus in either organ indicated removal of both. Of course not every collection of pus in the pelvis was tubal or ovarian, but if not, there would be absence of definite outline of the tumor.

Prognosis.—The eventual outcome of abscess of the ovary was usually like that of pus collections anywhere else in the body; the pus succeeded in forcing its way out in whatever direction there was least resistance. It might, however, take months, or even years. In rare instances the pus became cheesy and remained permanently. There was less danger of rupture than in abscess of the tube.

Causation.—The cause was usually inflammation coming up from the uterus and tube, hence the frequency of involvement of the organs on both sides. Of sixteen cases there was abscess of both ovaries in eight, of the left ovary alone in six, of the right alone in two.

Complications.—There was tendency to the formation of adhesions to the adjacent structures. Perforation into the gut would greatly endanger recovery. Systemic infection was rare since absorptive power of the abscess walls was slight. Perforation into the bladder or vagina might take place. If in perforation into the bowel the opening should be low, the drainage might be such as to permit of spontaneous closure, but if the opening were higher the dangers were likely to be enhanced by fecal matter entering the abscess cavity As to the significance of abscess of the ovary, it passed without saying that an ovary destroyed by suppuration was of no further use to

its possessor. An ovary in which all the Graafian follicles had been destroyed could never be rehabilitated.

Treatment.—The evacuation of the abscess was the treatment to be employed. This did not mean, however, that the abscess should be merely opened, the pus allowed to escape, and the cavity to close, as occurred in abscess of other parts of the body. The abdominal cavity should be opened, the sac enucleated together with the tube. Adhesions might make the operation difficult and dangerous. Generally, however, one could succeed in shelling out the abscess without rupturing the intestine or injuring neighboring organs. He cleansed the cavity with Thiersch's solution, then perhaps packed the seat of the abscess with iodoform gauze, one end of which was brought out of the lower angle of the abdominal wound. In Dr. Mundé's opinion this form of drainage constituted one of the greatest advances in abdominal surgery, without which he would now hardly know how to proceed in cases of extensive adhesions and oozing. He operated in Trendelenburg's posture, but flushed afterward in the ordinary position in order to avoid carrying infection up to the diaphragm. Only one of his sixteen patients died, septic peritonitis having developed.

Vaginal Drainage of Ovarian Abscess.—In a certain number of cases abdominal section was not necessary. He referred to those of long standing, where the whole pelvis was a masss of adhesions and the pus collection was low, so that it could be drained through the vagina with less danger than enucleation after cœliotomy. He did not doubt that in years gone by he had sometimes thus drained ovarian abscesses which he had attributed to pelvic cellulitis. Some had recommended dilatation of the opening where perforation had taken place into the bowel, but Dr. Mundé recommended making an opening into the vagina and encouraging that into the bowel to close. Likewise in vesical perforation.

Dr. Hanks thought that while we could not take too much care in making the diagnosis of the existence of pus in the pelvic cavity, it was not so important to say whether it was in the ovary or in the tube. In either case an operation would be called for, and both organs should be removed when it was necessary to excise one. It was less difficult to make out pus in one or both organs than to differentiate between ovarian abscess and hypertrophy of that organ. In abscess low in the pelvis, other things being equal, he preferred to drain through the vagina instead of through the abdominal opening. He agreed with the author, that some of these patients went about for a long time without apparent great danger, but one could not say how soon perforation might take place, or an acute condition arise which would greatly endanger life. The contained pus, though small in quantity, seemed to be highly virulent, for in one case operated upon by him contamination of the cavity with but a very small amount, caused death from sepsis in twenty hours after the operation, and in the case of another surgeon the patient died within thirty hours.

Dr. A. F. Currier thought the author had done well in giving warning not to attempt too much where all the pelvic organs were fused together, and advised puncture and drainage through the vagina when fluctuation was felt near the vault. Yet Dr. Currier's experience had been that patients were seldom cured in that way. Regarding cleansing the cavity during the operation of laparotomy, he thought that ordinarily it was better to use the dry gauze sponge instead of resorting to irrigation, since by the latter method there was danger of widely spreading the virulent elements. While gauze drainage could be properly highly praised in some regards, yet it was painful to remove after three or four days, and he therefore first gave a few whiffs of chloroform. Moreover, he thought it was more likely to result in a sinus than if a tube of small calibre were used.

Advocates Pelvic Drainage.—Dr. Egbert H. Grandin was glad to avail himself of the opportunity again to emphasize preference for the vaginal route in drainage in a certain proportion of cases of pelvic abscess. Notwithstanding the condemnation which this method had received, and was still receiving from some, he was satisfied of its superiority in a certain proportion of pelvic abscesses, whether connected with the ovary, tube, or other tissue, provided it were situated low. The aspirator was used as a guide, the opening was enlarged with the bistoury. It could be still farther dilated. The finger could then be introduced, and with it break up the pockets of pus, wash out, drain, and thus very favorable chances of cure would be given. If, however, the walls continued to discharge pus, and the tract would not heal, there would then be time to open the abdomen and enucleate the offending mass, and in doing so there would not be the danger of infecting the abdominal cavity which attended primary laparotomy.

Experience a Teacher of Doctor and Patient.—Dr. A. P. Dudley thought the time was approaching when every surgeon would make conservatism rather than radicalism his motto. If the after-histories of patients could be obtained, he believed surgeons would regret many of their operations. A number of his patients whose appendages he had removed had returned three, four, or five years afterward, expressing regret that the operation had been performed, for the reason that hot flashes had either not ceased or had come on. In this line the paper of Dr. Goodell, of Philadelphia, has proven a valuable lesson. Therefore, he believed that if patients could be relieved of their pus by any conservative method, it was better than extirpation of the appendages, since loss of the latter might lead to development or continuance of subjective symptoms, such as hot flashes. Dr. Dudley differed strongly from Dr. Currier with regard to sponging out of pus in the abdominal cavity, for such a step meant certain inoculation by the rubbing process. He never allowed himself to touch pus in the abdomen with dry sponge or anything hard. Use irrigation, floating the pus out, not carrying it in. The hot water also relieved the shock of the operation. If the case were one of abscess which called for abdominal section, it also called for drainage, and this he now carried through the cul-de-sac into the vagina, never through the abdominal wound. Gauze was employed. Vaginal hernia had not followed.

Feculent Odor in Ovarian Abscess.—Dr. Jarman made two statements and offered a query. The great majority of cases of ovarian abscess seemed to occur on the left side; in all cases which he had observed where the abscess was of any size, there was a distinctly feculent odor. This had not been observed in pyosalpinx. Was it not possible, therefore, that the feculent odor was due to juxtaposition of the ovary to the rectum?

Dr. Mundé closed the discussion. He felt that free drainage through the vagina would be the better plan, for pus would not run up hill more than would water. Regarding the virulence of the pus in ovarian abscesses, it did not seem to be great, for in none of his sixteen cases had he succeeded in removing the sac without rupturing it, yet only one patient had died. He agreed with Dr. Dudley in the use of water to cleanse the abdominal cavity, and in condemning the rubbing out of pus because of inoculation of the peritoneum on which it lay. Removal of the gauze drain caused pain only when done too soon.

Further Study of Occipito-posterior Positions.—Dr. S. Marx read the paper. (See page. 585)

Turn the Head and Body.—Dr. Egbert H. Grandin agreed with the author, that the course of labor made the diagnosis of occipito-posterior position more frequently than abdominal palpation. Nor was it always easy to make out the occipito-posterior position early by vaginal touch. If the woman had short, nagging pains, one should think of occipito-posterior position at the brim, and on confirming the diagnosis he should rectify the position before the head engaged by turning the head and body into the anterior position, and maintaining it until a uterine contraction prevented return. If this

failed, resort to version rather than forceps. This was not the first occasion when Dr. Grandin had emphasized the practicality and advantage of correcting the faulty position before the head had engaged, and he thought the author's failure must have been due to neglecting the precaution of holding the body and head in the corrected position until uterine contractions had taken place and fixed it. By this measure one obviated those serious dangers attending engagement of the head in the occipito-posterior position, one of which was prolonged pressure upon the fœtal brain, which led oftener than physicians had realized to nervous diseases like epilepsy and idiocy. Dr. Grandin differed from the author who had spoken of high forceps when the head had engaged, Dr. Grandin regarding this as medium forceps, whereas high forceps meant the application of the instrument while the head was still movable above the brim. He preferred version to high forceps. When medium forceps was called for version was impossible, because the head had already become fixed, and he did not believe that with forceps turning would be accomplished unless the head were small.

A Large Experience.—After Dr. Currier related experience with two cases, showing that the abnormal course of the labor was apt to be the cause of recognition of the occipito-posterior position, Dr. Tucker stated that he had observed 150 cases of occipito posterior position, and that diagnosis had become certain with him only after the skill acquired by seeing thirty cases. Where the head was above the brim he saw no need of rectifying the position, as nearly always it settled down into the pelvis in either the transverse or oblique position. Where the head had engaged, no one would think of using the hand, but would employ forceps.

Dr. Collyer thought an experience of 150 cases rather exceptional, since statistics gave, he believed, only about one case of occipito-posterior position in 50 labors. He recommended version in preference to high forceps.

Diagnosis by Examination Possible.—Dr. Brooks H. Wells had found it quite possible to make the diagnosis of the position under question by abdominal and vaginal palpation, provided it were gone about systematically and properly. Barring deformities and abnormalities, rotation usually occurred by the time the head reached the pelvic floor.

Dr. Jarman said that by following the instructions which Dr. Grandin had repeatedly given, anyone could learn to correct the occipito-posterior position and maintain it before engagement by turning the body with the head. Such had been the experience of the house staff at the City Maternity.

The Chairman, Dr. McLean, said he had read a paper some years ago when such authorities as Isaac E. Taylor, Lusk, and others were present, and his statement, that there was no teacher of obstetrics who could positively make the diagnosis of the occipito posterior position by vaginal touch alone, went unchallenged. It could be made, however, by the peculiar behavior of the labor, by vaginal and abdominal palpation, especially by touching the ear. He thought Dr. Tucker had misunderstood the question: the cases under discussion were those of occipito-posterior position causing symptoms or abnormal labor. His own views were precisely in accord with Dr. Grandin's regarding the success of turning the head and body into the anterior position, and holding it there until it had become fixed by a pain.

The Army Medical Department in Germany.—Nine posts for surgeon majors are about to be added to Frederick William Institute of Military Medicine. It has been thought necessary to take this step in order to provide means whereby army doctors may improve their knowledge of military surgery, and also acquire proficiency in certain specialties, such as mental, nervous, and ophthalmic diseases, as well as in advanced hygiene and bacteriology.

Reviews and Notices.

Memoranda on Poisons. By Thomas Hawkes Tanner, M.D., F.L.S. Seventh American, from the last London, edition. Philadelphia: P. Blakiston, Son & Co. 1892.

The fact of any technical work, great or small, reaching its seventh edition speaks for itself. In the most condensed form are given the history of poisons, their antidotes, and various mechanical methods for overcoming the tendency toward death. The principal changes in the new edition have been the substitution of modern chemical nomenclature and the omission of obsolete portions of the old text. The toxicology of poisonous food has been presented as fully as the concise character of the book allows. As the work is intended for those engaged in actual medical practice, and not for medico-legal reference, the English cases, as a rule, have been omitted.

Lectures on Mental Diseases: Designed especially for Medical Students and General Practitioners. By Henry Putnam Stearns, A.M., M.D., Physician Superintendent of the Hartford Retreat, etc. Philadelphia: P. Blakiston, Son & Co. 1893.

These lectures have been prepared as the basis for instruction in mental disease to the medical students of Yale University. They are based upon the teachings of Ball, Dagonet, Voisin, Griesinger, Obersteiner, Lewis, Maudsley, Spitzka, and Tuke and Bucknill. Three of the illustrations are from Blackburn's "Manual of Autopsies," and twelve from Obersteiner's work on Central Nervous Organs. The appendix comprises the most important parts of the laws of the several States and Territories relating to the duties and responsibilities of physicians concerning the insane at the present time. The classification of insanity that is suggested embraces five divisions that are symptomatological: Melancholia, mania, primary delusional insanity, *folie circulaire*, and dementia. There are twenty forms in the etiological division, grouped into six classes: Epochal, sympathetic, toxic, neuropathic, pathological, and other less frequent genera and species. The lectures are clear and well written, and embody the prominent ideas that now prevail in psychiatry.

The Diseases of the Nervous System: A Text-Book for Physicians and Students. By Dr. Ludwig Hirt, Professor at the University of Breslau. With 178 illustrations. New York: D. Appleton & Co. 1893.

In this book nervous disorders are considered under the following heads: Diseases of the Brain and its Meninges, including those of the Cranial Nerves; Diseases of the Spinal Cord; and Diseases of the General Nervous System. Of the latter two divisions are made—those without recognizable anatomical basis or functional neuroses, and those with known anatomical basis, viz., multiple sclerosis, tabes dorsalis, general paralysis of the insane, syphilis of the nervous system, and intoxication paralysis. The illustrations are clear, typical, and, for the most part, unfamiliar to American books. While not all original, they are copied from non-English authors. The style is plain and forceful, and at no point is there the slightest doubt of the writer's meaning. In the preface he states that "only too well aware of his shortcomings, he is convinced that he has set down concisely what he has learned from others and observed himself in an extensive hospital as well as private practice." The following, concerning the pathology of chorea, is an interesting example of the dispassionate quality of the author's mind, and the clear and forceful exposition of his views: "Our knowledge of the pathology of idiopathic, uncomplicated chorea is very imperfect. Repeatedly capillary emboli have been found at the autopsy in the thalamus and the corpus striatum;

often they could not be demonstrated. The experiments of Money on guinea-pigs and dogs would indicate, very decidedly, that chorea can be caused by capillary emboli. Their mode of action, however, remains unexplained. The objections which Litten has raised against the emboli theory, that the demonstration of emboli processes in ordinary cases of chorea is not proved, and that in spite of the diversity of the localization of the foci of softening in the brain the clinical picture is always the same, cannot be regarded as convincing. The communication of Flechsig, who in the two inner segments of the lenticular nucleus, but nowhere else, found small bodies in the lymph sheaths of the vessels, some of which were larger, some smaller than blood-corpuscles, has since been neither confirmed nor overthrown. 'Their arrangement resembled that of glandular structures; they were strongly refractive, very firm, and almost like chalk, although they contained no lime. In alkalies they slowly swelled.' Though their chemical nature is unknown, they resemble in the main that material which von Recklinghausen has termed 'hyaline.' This observation has not as yet been interpreted, and Flechsig himself declines to give a decided opinion as to whether the bodies have been formed in the blood or lymph vessels, or whether they have to be regarded as products of degeneration from ganglionic cells and nerve fibres. Although we have to admit that lesions in the lenticular nucleus may cause choreic movements, we can as yet make little use of these bodies as an anatomical cause for the disease. . . . Although we are thus still unable to say anything definite about the nature of the disease, the assumption that we have before us an affection of the entire nervous system, in which, to be sure, the brain takes the most prominent part, seems the most probable. Whether certain portions of the brain are particularly qualified to produce choreic movements, whether, besides being produced by irritation of the cortical motor centres, they may also be brought about by lesions of the basal ganglia; further, whether this irritation can ever be attributed to infectious material, microbes, or the like; or whether it can ever be connected with fungous growths, such as Naunyn has found in the pia, and belonging to the species of the cadothrix or leptothrix—all these remain open questions, and we must also leave undecided whether or not the alteration of the blood depending upon the so-called rheumatic diathesis is sufficient for the development of chorea." Concerning hypnotism the author shows an open mental attitude. "We must recognize here indications and contra-indications. . . . Even the smallest operation—that of vaccination for example—has to be learned, so the art of hypnotizing has to be acquired, and one can expect to comprehend the subject and to have success with the practice of the treatment by suggestion only after careful and painstaking study. . . . We must still be very careful in accepting the accounts of the influence of hypnotism upon hystero-epilepsy, and the conditions produced thereby. . . . What, then, are the diseases in which we can, with good conscience and good hopes of success, venture to employ the treatment by suggestion? Inflammatory processes, new growths, infections, or, in a word, organic lesions, do not belong to this class. It is a different matter if we are dealing merely with certain symptoms of such maladies, for instance, insomnia, difficulty in breathing, or pains of the most varied kind, not excluding the lancinating pains of tabes. Here hypnotism should at least be given a trial. Yet the main field in which treatment by suggestion should be employed is not in the diseases here mentioned, but rather all those which we have designated as functional disorders of the nervous system. Here motor as well as sensory disturbances can be influenced, various neuralgias, including tic douloureux, writer's cramp, chorea, the tremor of paralysis agitans, and so forth."

At the end of every subject treated in this text-book a comprehensive list of the most important references is given, of great use for further investigation. It is a delightful book to study, and of the utmost value to the general practitioner.

A Text-book of the Physiological Chemistry of the Animal Body; including an Account of the Chemical Changes occurring in Disease. By Arthur Gamgee, M.D., F.R.S. Vol. II., the Physiology of Digestion. Pp. 528. London: Macmillan & Co. 1893.

This is the second volume of a work, the first volume of which appeared in 1880. The present work, however, like its predecessor, is a complete treatise by itself, and deals only with the chemistry of digestion. This subject is dealt with most exhaustively. Dr. Gamgee gives not only the chemistry, but the anatomy and physiology of the parts, and we can hardly imagine of a single item in the whole range of the digestive processes that is not touched upon. The composition, function, and methods of testing are all given in careful detail. The book is necessarily technical, and is one that will be of especial service to an advanced worker. But as a manual of reference its value, even to the practising physician, must be great.

A Manual of Physics. Being an Introduction to the Study of Physical Science, designed for the Use of University Students. By William Peddie, D.Sc., F.R.S.E. New York: G. P. Putnam's Sons. London: Baillière, Tindall & Cox.

This is a small volume that gives, as far as possible, a review of the elements of physics, keeping in mind the essential unity and interdependence of the various branches of the whole subject. There are many illustrations, mathematical calculations, and a careful consideration of scientific hypotheses, concerning which ordinary notions are somewhat hazy. There are interesting chapters on electrostatics, thermo-electricity, and electric currents. The "Manual" is convenient in size, well printed, and has the available index dear to the real student's heart. Possibly too much has been attempted for a work of the kind, the subject naturally falling into special branches that are each of great importance. Yet the main points of these are carefully given and the book is distinctly useful.

Diseases of the Rectum and Anus. Their Pathology, Diagnosis, and Treatment. By Charles B. Kelsey, A.M., M.D., New York; Professor of Diseases of the Rectum at New York Post graduate Medical School and Hospital, etc. Fourth Edition, revised and enlarged. New York: William Wood & Co. 1893.

A fourth edition speaks for itself. This one contains two chromo lithographic plates and one hundred and sixty-two illustrations. The teaching is practical, and the author's reputation as an authority is sure to secure for this, as for other editions of his work, a ready and gratifying sale.

A Primer of Psychology and Mental Disease. By C. B. Burr, M.D., Medical Superintendent of the Eastern Michigan Asylum, etc. 1894. George S. Davis, Detroit, Mich.

Divided into three parts, the first treating of psychology, the second describing and defining different forms of insanity, and the third devoted to the management of cases of insanity, this primer contains, in very simple paragraphs, much information of value to those in charge of the insane. It is characterized throughout by sound common-sense. There is in it all that an attendant need know concerning normal mental processes and the manifestations of the unsound mind. Directions for the daily and constant care of the insane; for the administration of food and medicine; for exercise, employment, and diversion; for correcting pernicious habits and for checking morbid impulses, are given with force and clearness. The "Primer" is designed for training-schools, for the attendant "who is the agent of the people and represents them." There is an admirable index, by which the material in the book is rendered perfectly available.

Methods of Pathological Histology. By C. Von Kahlden. Translated and edited by H. Morley Fletcher, M.A., M.D., with an Introduction by G. Sims Woodhead, M D. London and New York: Macmillan & Co. 1894.

This manual of methods was first issued as a supplement to Ziegler's "Allgemeine und specielle Pathologische Anatomie," later in a separate form, and is now introduced for the first time in an English dress. The busy student who wishes to utilize it with the least possible expenditure of time and trouble, has now free access to the valuable directions of Von Kahlden. In the form of footnotes the editor gives additions and modifications of great practical value, the results of his own experience, that bring the book well up to date. There are chapters on the microscope and apparatus requisite for histological work, examination of fresh tissues, methods of hardening, decalcification of tissues, methods of embedding, injection of tissues, preparing and mounting sections, staining processes, bacteria, moulds, fungi, animal parasites, and microscopical examinations for medico-legal purposes. This work on "Methods" is plain, practical, comprehensive, and complete. It recommends itself to everyone engaged in histological research.

Transactions of the Third Annual Meeting of the Association of Military Surgeons of the National Guard of the United States.

One of the most important papers in this report is that on Enterorrhaphy, giving the history, technique, and present status, by Colonel Nicholas Senn. It is freely illustrated. Other papers of interest will be found relating to gunshot wounds and other subjects connected with military surgery.

Æro-Therapeutics; or, The Treatment of Lung Diseases by Climate, being the Lumleian Lectures for 1893, delivered before the Royal College of Physicians, with an Address on the High Altitudes of Colorado. By Charles Theodore Williams, M.A., M.D. Oxon., F.R.C.P.; Senior Surgeon to the Hospital for Consumption and Diseases of the Chest, Brompton; Late President of the Royal Meteorological Society. London and New York: Macmillan & Co. 1894.

These lectures take up the factors and elements of climate, temperature and moisture, barometric pressure in its relation to health and disease; and the climates of Colorado.

In the first lecture Madeira, the Canary Islands, Teneriffe, and Egypt, are incidentally discussed as suitable resorts for the consumptive. In the second, the Riviera, Algiers, Southern California, the cold climates of Minnesota and Canada, sea voyages, etc. In the third, the therapeutic uses of compressed air are taken up, together with mountain-climbing and high-altitude sanitaria. The author here cites two hundred and forty-seven cases showing the effect of high altitudes. Anyone at all interested in the climate treatment of phthisis will find enough in these 185 octavo pages amply to repay him.

The Diseases of the Hair and Scalp. A Practical Treatise. By George Thomas Jackson, M.D., Professor of Dermatology, Woman's Medical College, New York Infirmary; Chief of Clinic and Instructor in Dermatology, College of Physicians and Surgeons; Consulting Dermatologist, Presbyterian Hospital; Visiting Dermatologist, Randall's Island Hospital, etc. New, Revised, and Enlarged Edition. New York: E. B. Treat. 1894.

If, in the years intervening since Dr. Jackson wrote his first preface, in 1887, he or anyone else had discovered how to make hair grow upon the average every-day bald head, and the secret were here recorded, this book would meet with such a sale as never book had before. Diseases of the scalp whose etiology is known are less common. Some advances have been made in the past seven years, and these are reflected in the new chapters upon folliculitis decalvans, leptothrix, and aplasia pilorum propria (which would seem to be rather a deformity than a disease), as well as in important additions to the articles upon the parasitic diseases, alopecias, seborrhœas, and others. The author still clings to the trophoneurotic theory of alopecia areata, and lays little stress upon the belief now held by many, that there are at least two forms of alopecia areata, one of which is parasitic and another neurotic. Still, on page 123, he says: "It is probably best to hold that there are some cases that are contagious and maybe parasitic."

The improvements over the first edition consist principally in a record of the observations of others, made in the various departments since 1887, bringing the matter more up to date. Some new wood-cuts have been added, but the illustrations could never lay great claim to beauty or finish.

The Medical Annual for 1894. Pp. 672. Bristol: John Wright & Co. New York: E. B. Treat. 1894.

This is the twelfth year of this useful publication. In general arrangement the plan is the same as in former years, except that the more important contributions to medical science during the year appear in the form of communications from those who originally made them. While only a comparatively small field can be covered in this way, the work will serve as a very good epitome of progress for the past year. The illustrations are excellent.

A Manual of Diseases of the Ear. By George P. Field, M.R.C.S., Aural Surgeon to St. Mark's Hospital; Lecturer on Aural Surgery and Dean of the Medical School. Fourth edition, pp. 382. Philadelphia: Lea Brothers & Co.

The first edition of this "Manual" came out in 1876, and was quickly followed by the second in 1879; while the present, or fourth, edition appeared late in 1893. Its special features are "its lucid exposition" of the etiological and pathological factors of aural disease; its brief and pointed demonstrations of the anatomy of the regions involved, and the novel and striking wood-cuts and chromo lithographs accompanying the text. The author is well known to the seekers of otological literature in this country, and it goes without saying that he is better known in the British domain. His experience has been large, and this "Manual" shows that its results are methodically classified. From this stand-point the work is an addition to the literature of the subject.

Its chief value may be said to be to the student and general practitioner. It is too short to enter fully into questions of debatable interest, or to include recent valuable contributions to clinical experience. The special student in aural therapeutics and surgery must look to text-books and journalistic literature of our own country for the most recent additions to these departments.

New Truths in Ophthalmology. By G. C. Savage, M.D., Professor of Ophthalmology in the Medical Departments of the University of Nashville and Vanderbilt University. Pp. 152. Nashville, Tenn. 1893.

This series of monographs on stray and abstruse subjects of ophthalmology has appeared from time to time in the *Ophthalmic Record*, a monthly publication of the same author. The names of the following chapters will give an idea of the scope and trend of the book: The Harmonious Symmetric Action of the Oblique Muscles in all Cases of Oblique Astigmatism; Insufficiencies of the Oblique Muscles, and How to Correct Them; Rhythmic Exercise, the Proper Method of Developing the Ocular Muscles; The Monoscopter; Heterophoria, and a Safe Line Drawn between Operative and Non-operative Cases; the Author's Method of Operating; Muscle Shortening *vs.* Muscle Advancement.

The monographs are of chief interest to physicists and oculists, and recall lively discussions in the American Ophthalmological Society and similar scientific bodies.

The author has added some personal notes on operations for the advancement of some of the ocular muscles, pterygium, artificial pupil, entropion, and narrowing of the fissure between the lids.

A Manual of Practical Obstetrics. By Edward P. Davis, A.M., M.D., Professor of Obstetrics and Diseases of Infancy, Philadelphia Polyclinic. Second edition. 8vo, pp. 351. Philadelphia: P. Blakiston, Son & Co. 1894.

We have so recently reviewed this excellent work that it is only necessary to reiterate our opinion of its practical merits, and call attention to the fact that in this edition symphyseotomy is fully considered, and some interesting points in connection with obstetric palpation are further elaborated.

Lectures on Surgery. By David W. Cheever, A.B., M.D. (Harv.), Professor of Surgery, Emeritus, Medical School of Harvard, etc. 12mo, pp. 591. Boston: Damrell & Upham. 1894.

The book contains didactic lectures, stenographically reported, which are part of a course delivered at the Medical School of Harvard. The author is so well known to the readers of surgical literature as an accomplished, original, and practical surgeon, that it is unnecessary to predicate that his teachings are in the highest degree valuable, and that his methods of practice are based on the large and varied experiences of a successful operator. As a lecturer for over a quarter of a century, it is fair to presume that he understands the needs of the student and general practitioner. In this respect the reader will be in no manner disappointed. The style is entertaining and lucid, the descriptions vivid and to the point, and the conclusions are convincingly logical. It is, in fact, a charming and practical talk, full of pith and suggestive expedients concerning the commoner surgical difficulties which fall in the way of the general practitioner. The subjects treated are: Anæsthetics; Delirium Tremens; Gunshot Wounds; Injuries of Blood-vessels; Fractures; Dislocations; Frostbites and Burns; Injuries of the Head; Injuries of the Spine; Foreign Substances in the Throat; Wounds of the Face, Throat, and Abdomen; Surgical Diseases of the Blood vessels; Aneurisms; Diseases of the Bones and Joints, and Surgical Diseases of the Nose, Lips, Mouth, Throat, Rectum, Bladder, Urethra, and Scrotum, including the Surgical treatment of Hernia.

The subjects are well selected, and treated as they are from a practical stand-point, cannot fail in being interesting and instructive. The reasons for treatment are so well founded on the broad principles of sound surgical procedure, that the reader is impressed, edified, and instructed. We are struck particularly with the large amount of suggestive comment and practical interpolation that occurs everywhere in the text—so much so that even the experienced reader is often forced to admit that he has never had this or that particular idea presented to him in that way before. The book is small, but no space is wasted. We only wish that the author's course had been longer.

The Anatomy and Surgical Treatment of Hernia. By H. O. Marcy, A.M., M.D., LL.D., of Boston. Published by D. Appleton & Co.

Dr. Marcy says, in offering this work to the profession, he has been actuated by the belief that there exists the necessity for the better instruction of the surgeon, as well as of the general practitioner, upon the anatomy and surgical treatment of hernia.

The book is profusely illustrated, giving excellent reproductions of many of the older writers, and descriptions of most of the more modern operations.

The author claims that the method of Bassini is quite similar to his own, that of reconstructing the inguinal. The description and plates given of Dr. Marcy's operation are confusing, certainly not so easily understood as the method of Bassini.

The new suture material, kangaroo tendon, is excellent for hernia operations, as it is stronger and takes longer to be absorbed than catgut.

Too little consideration has been given the mechanical treatment of hernia, to make the book of the greatest practical value to the general practitioner or surgeon, and we feel that in this day of practical work the author could have quoted less and yet not detracted from the usefulness of the book.

Transactions of the Southern Surgical and Gynecological Association. Vol. VI. Sixth Session. 8vo, pp. 392. Published by the Association. 1894.

This volume is uniform with the previous series, and contains the usual amount and variety of matter in general surgical and gynecological subjects. Abdominal and uterine surgery claim their share, and appendicitis is twice heard in two excellent papers. In fact, all the papers are of excellent quality and give a real value to the book as a whole, differing, perhaps, in this respect, from many other publications of the kind.

Lectures on Genito-urinary Diseases. By J. C. Ogilvie Well, M.D., C.M., F.R.S.E., Consulting Surgeon Aberdeen Royal Infirmary. 8vo, pp. 142. London: The Scientific Press, Limited.

This book contains lectures on "Urethral and Catheter Fever," "The Treatment of Retention of Urine," "Gleet and its Treatment," "Varicocele, Hydrocele, and the Treatment of Syphilis." Of these the lecture on the first subject is particularly interesting, embodying much information and many original observations. Of the others it can be said that their treatment is in accordance with that at present in vogue. The book contains an admirably executed chromo-lithographic plate illustrating the different forms of pyo-nephritis.

The Physician's Bedside Record, with Dietary. By Gideon C. Segur, M.D. Hartford: Plimpton Co. 1889.

The usual chart arrangement for bedside use, with a number of good recipes for preparing foods for the sick.

Transactions of the American Dermatological Association for 1893. Pp. 82. Two Colored Plates. Edited by the Secretary, George Thomas Jackson, M.D. New York. 1894.

Eight papers are printed at length with ensuing discussions. There are also minutes of general discussions on pityriasis rosea and pemphigus. Statistical tables, and a yearly bibliography of the writings of members, close the volume.

Cresilol as an Anatomical Preservative.—Dr. Ramon Timenez, of Madrid, read a paper with this title at the Rome Congress, of which the following were the conclusions: 1. Cresilol, being an injection with glycerine and alcoholic base, must necessarily be very penetrating, and therefore solves the problem of reaching the most remote tissues, removing the danger of partial putrefaction. 2. Being much less toxic than carbolic acid it exposes the dissector to no danger, and, as its caustic action is also less, it does not injure the instruments as much as does carbolic acid or corrosive sublimate. 3. It alters to a very slight degree the color of the tissues, a matter of great importance in museum specimens, and also does not coagulate the blood. 4. It preserves a cadaver perfectly in the open air for at least six months, and, when it is enclosed in a casket for a year, the natural appearance and color are for the most part retained. 5. A regularity in the subsequent phenomena of mortification is observed which is obtained after the use of none of the other preservative methods. 6. In preparations in which cresilol has been employed the flexibility and normal volume may be restored by steaming with warm vapor, and thus they may be restored to a condition very similar to that of fresh specimens.

London, April 14, 1894.

Undoubtedly the event of the week has been the extraordinary meeting of convocation of the London University held on Tuesday to consider the proposals of the Gresham Commission. Although the present university is so much identified with medicine much of the agitation for another foundation arises from its absurd regulations making the attainment of medical degrees difficult. The Senate has not merely raised the standard of examination unduly—which may be of use—but interposed regulations which prevent hundreds from presenting themselves. I do not say this at random, for an experience of more than a quarter of a century as a teacher in London has given me sufficient information as to these points. But to the meeting. Well may it be said to have been rather excited, not to say stormy. Two opposing opinions prevail in convocation, and this meeting was largely attended by both parties. The prevalent view would most likely be in favor of enlarging the constitution of the present university so as to secure all the academic influence of the metropolis. But there seems unreasonable terror among the graduates lest the value of their degrees should be depreciated. On the one hand, it is obvious that the university has up to now been a mere examining body governed by the Senate, while the graduates (of which convocation consists) have no power except to decline accepting a new charter. The Senate and convocation have not worked harmoniously, but now that there is some prospect of legislation coercing both the common danger seems to have shown the two bodies the necessity of consideration. Accordingly after various resolutions and amendments had been proposed and discussed with a warmth scarcely suggestive of academical calm, it was agreed to invite the Senate to meet convocation in a joint committee to consider the Gresham scheme. The next day a meeting of a committee of the Senate appointed to consider this scheme took place and decided to express no opinion, but to recommened the appointment of delegates to the proposed joint committee of Senate and convocation. This plan will probably be adopted and some form of action agreed upon by the two bodies.

At the Medico Chirurgical Society, on April 10th, Mr. Herbert Durham achieved a considerable success with a paper on Persistent Thyreoglossal Duct. Three cases were described, with special reference to the histological character of the specimens removed. It was suggested that many cases which have been regarded as bronchial fistulæ were of the same nature, and interesting remarks on median cervical cysts and fistula were offered. The author had the good fortune to be complimented by both Mr. Bland Sutton and Mr. Raymond Johnson, both of whom are entitled to be considered authorities on the matter. Some doubt was expressed as to Mr. Marshall's well-known case, and Mr. Herbert Durham thought it might possibly be a persistent sinus præcervicalis. A difference of opinion, curiously enough, was also expressed as to whether the thyreoglossal duct could be seen by the naked eye or required a microscope to detect it by finding its characteristic epithelium.

At the last meeting of the Obstetrical Society Dr. Amand Routh brought forward three cases of associated vaginal and parovarian cysts and suggested distension of Gartner's duct as the explanation. This duct may sometimes be traced in the adult from the parovarium to the vertibulum valvæ, beneath and to one side of the urethral orifice. Dr. Routh thinks there is reason to believe that Skene's ducts are not identical with the anterior termination of Gartner's, and that if the latter be patent it may become distended in any part of its course and so form a parovarian or a vaginal cyst. In his cases both forms were present. He advised opening the vaginal portion and allowing the other to contract and close up. Some interesting remarks were made by several speakers, one of whom thought vaginal cysts were not so rare as commonly supposed, for he had met with six cases in the last twelve months. Messrs. B. Sutton and A. Doran and the president (Dr. Herman) agreed in the main with Dr. Routh and expressed appreciation of his exact observations on this difficult subject.

The law courts have again furnished material for reflection by the profession. A respected medical man has been made a co-respondent in the Divorce Court, and athough the case was dismissed and the jury expressed deep sympathy with the doctor in the unfound charge, and the judge said he was glad of this expression, in which he fully concurred, we may well ask whether some redress should not be obtainable in such cases. In our professional work we are peculiarly exposed to attempts at blackmail, and if lawyers are right when they say there is a remedy against every wrong, such abominable charges ought to entail full responsibility. The punishment of perjury for those who make them without any foundation would be appropriate.

An action for libel arising out of remarks by one doctor on another commencing practice where he had been an assistant and had signed a bond not to do so has also been decided. The point urged about the bond was that the death of the master was believed by the assistant to release him from the obligation. Drawers of bonds will probably take care to be explicit on this point in future.

Another case heard lately was a charge against a surgeon by a nurse who had been operated on. She declared the surgeon had promised to carry the operation to a certain extent only, but had gone beyond. The jury justified the operator, and the judge told the nurse, now she had ventilated her grievance, he trusted she would think better of the surgeon. Here is another case showing what annoyance and loss may occur through the unfounded suspicion of a patient—and a gratuitous one to boot. Such cases have occurred too often, and the lawyers ought to tell us the remedy for the wrongs.

The Court of Appeal on Tuesday pronounced the Lanolin patent to be valid. Reliance on the objector's part was largely placed on the remarks of *Dioscorides anent Œsipus*. It was, I fancy, the patentees who first of late years circulated the quotation from the Greek author which was employed to assail their patent.

Dr. Arthur Hill Hassall died on Tuesday last at a good old age, having been born in 1817. He was of somewhat delicate constitution, and in 1866 was attacked by hæmoptysis. He thereupon went to the Undercliffe and established the National Hospital for Consumption on the separate principle Later he retired to San Remo. Last year he published his "Narrative of a Busy Life." He was at one time regarded chiefly as an authority on adulteration of foods, as he was employed by *The Lancet* on its well-known sanitary commission. Indeed, he assumed all the credit of that important work, although, as is well known, other men did all the most difficult work.

I may also report the death of Dr. J. M. Bryan, of Northampton, where he began practice in 1835. He died lately, at the age of eighty-four, universally respected.

London, April 21, 1894.

The allegations made some time since against the Forest Gate School have been to a considerable extent corroborated, and the local Government Board has given a decision which by no means exonerates, but rather condemns, the management. As the school accommodates seven hundred children it is an important case. The district comprises two unions, so that the guardians can only act indirectly, but they will probably very soon take means to let the public know what authority they have exercised.

In Parliament there has not been much of medical interest lately, but the societies have been particularly busy, as is often the case toward the end of the session.

At the Pathological Society, on the 17th, Mr. Charters Symonds reported a case of squamous-celled carcinoma of the bladder, the greater part of which was removed by suprapubic operation. This gave the patient much relief, but suppuration insued in the affected inguinal glands while cellulitis and death followed from pyæmia. Secondary growths were found at the autopsy in the liver and lungs.

Dr. P. Abraham and Mr. L. Bidwell showed microscopic sections of the skin after Thiersch's grafts. The graft was implanted in December, 1892, after excision of lupus, and about two-thirds of it "took" and the rest of the surface healed by granulation. Some of the new skin, including a part of the graft, was removed nine months later on account of recurrence. In the position of the graft a definite cutis was found with well formed papillæ, but neither hairs nor glands; while the subjacent tissue seemed richer in cells than it is normally. Sensibility had become pretty normal in the graft, as has been observed in other cases.

A specimen of melanotic sarcoma of the rectum was then shown. This is one of the commoner primary seats of this disease, and it was remarked that gray horses are very liable to it.

Mr. Shattock exhibited some specimens of ectopia vesicæ, and pointed out that the muscular wall of the bladder was firmly attached to the separated surfaces of the pubic bones, and this he had found to be the case in all his dissections corresponding with the attachment of the normal pubo-vesical muscles. But it was even more obvious, and although the bladder being in such cases not a hollow organ and therefore not having expulsive power, the muscular tissue was hypertrophied instead of the reverse. This he supposed to result from resistance to hernial protrusion, the vesicle wall becoming in fact a part of the abdominal parietes. Another preparation showed the effect of ectopia on the spongy and cavernous bodies.

Aberrant renal vessels, supernumerary adrenal, fat necrosis and pulmonary gangrene formed the remainder of the pathological entertainment.

At the Medical Society Mr. Keetley showed two lads on whom he had operated for undescended testes. He brings down the organ, and sutures it to a skin wound in the scrotum and neighboring part of the thigh, the sutures piercing the tunica vaginalis. In one case the testes was left thus fixed for five months and then separated.

Mr. H. Fenwick showed a man, aged thirty-eight, from whom he had removed the testes, scrotum, and penis, down to the perinæum, for epithelioma by the Thiersch-Gould method. The wound healed at once, and the man is in good health at present. He also showed papillomata from the urethra of a man who had had an obstinate gleet. He further showed an instrument combining a sound and cannula with a straight cystoscope, for the purpose of exploring or draining the bladder through a suprapubic trocar puncture in cases in which urethral cystoscopy could not be carried out in consequence of enlarged prostate.

A case of paralysis of the sterno mastoid, trapezius, and right side of the face in a married woman, aged nineteen, was brought forward by Dr. Lewis Jones. The accessory to the vagus and the hypoglossal had escaped—a rare event. A case of osteitis deformans dating from an injury to the thigh and one of nævus cured by electrolysis complete the exhibits.

At the Clinical Society Mr. G. B. Turner read an account of a case of pelvic enchondroma which had been shown at the Society in March, 1890, when it was generally thought unadvisable to attempt to remove it. It, however, steadily grew, and in 1892 pressed on the urethra and perinæum so as to interfere with micturition and defecation. It was then successfully removed in two halves and weighed above seven pounds.

Some conversation took place on continuance of obstruction of the bowels after operation for hernia, originating in notes of a case read by Mr. R. W. Parker. In his case the intestine at an herniotomy being found in a state of gangrene he made artificial anus, but no fæces escaped, and after sixteen hours laparotomy was performed, as the abdomen was more distended. Remarks were made as to the slight amount of twist that sufficed to produce obstruction and the propriety of surgical relief. The advantage of early operation was also strongly insisted on.

Three other subjects were crowded into this evening's meeting, but cannot be crowded into this letter.

THE STATUS OF MEDICAL LEGISLATION IN UTAH.

To the Editor of the Medical Record.

Sir: Since the appearance of the report of the Illinois State Board of Health for 1893, and the editorial review of the Medical Record of the same, the legal requirements for the practice of medicine in the Territory of Utah have undergone a change at the hands of the recent legislature. The amendments to the old law, which was a good one although far from satisfactory, seem to be for the better, as they meet admirably the peculiar local conditions.

To review these changes and show the progress made in this department of medical legislation, is the object of this communication, which will be of interest to medical men in general, that in the far-away Utah the standard requisite for the practice of medicine is on a par with that in those States in which are to be found our greatest medical centres. No diploma confers the right to practise medicine, but an absolutely independent examination, conducted wholly or partially in writing.

In this connection it is encouraging to note the strong conviction among the people in its favor, and the great willingness on the part of the legislators to elevate the standard of medical requirements, and bring within the bounds of the Territory first-class men.

The Board of Medical Examiners consists of seven members appointed by the Governor and confirmed by the Legislative Council, who hold office for two years, or until their successors are appointed and qualified. They elect their own president, secretary, and treasurer, and attest their official acts under their own seal. Of the Board, four members are of the regular school of medicine, two of the homœopathic, and one of the eclectic schools, all of whom are working in perfect harmony to the end that the communities may have a reasonable amount of protection against incompetency and quackery.

The Board issues two forms of certificates, one for those who have been examined and favorably passed upon, and the other for non-graduates, as described later. Still another form of certificate is issued to those desiring to practise obstetrics after passing a satisfactory examination. These certificates must be recorded within three months after the date of issue, in the office of the recorder of the county in which the holder resides, and until such certificates are recorded the holder cannot exercise any of their privileges. It is further stated that the county recorder shall keep in a suitable book a complete list of the certificates recorded by him, with the date of the issue of

the certificate; and if the certificate be based upon a degree and examination, he shall record the medical college conferring the degree and the date of the same. This register shall be kept open to the inspection of the public, so that at any time one can find the basis upon which a practitioner has gained his license.

The Board has the power to refuse to issue a certificate, and to revoke a certificate once issued, to persons guilty of immoral or dishonorable conduct, the nature of which must be stated in writing; and in all cases of refusal or revocation the applicant may appeal to the Chief Justice of the Territory, who may affirm or overrule the decision of the Board.

As to who shall be licensed, the bill states that graduates of respectable medical colleges who were engaged in actual practice in this Territory prior to March 10, 1892, shall be licensed to practise medicine upon presentation of their diploma, and giving satisfactory evidence of the identity of the applicant. The term, respectable "medical colleges," in this bill, includes colleges in good standing in the States where they exist, or recognized by the examining boards of the States wherein they exist.

As to non-graduates of medical colleges, those who have practised five years continuously in this Territory prior to the passage of this act can, by producing to the Board of Medical Examiners a proper application, accompanied by a petition signed by twenty-five legal voters living in the city or precinct where the applicant resides, and on the payment of a fee, receive a license to practise medicine in the city, county, or precinct where the signers of the applicant's petition reside. But the non graduate so receiving his license to practise medicine, shall not in any way advertise as a doctor, physician, or surgeon, by either sign or card, but may, if he advertise at all, do so as a licensed non-graduate practitioner of medicine.

Thus it may be seen that the bill is much more for the future than for the present, since the non-graduate practitioner of medicine in this Territory will in the course of a limited time be a thing of the past.

The clause as relative to the non-graduate was introduced in deference to certain isolated settlements incapable of supporting an educated physician, and whose only medical assistance is the non-graduate, or perhaps some woman in the practice of obstetrics.

The preceding, of course, affected only those who were actually engaged in practice prior to the passage of the bill. From the approval of the bill, March 8, 1894, all alike must pass an independent examination. To the graduate of a medical college his diploma simply admits him to examination, while the non-graduate, to be admitted to the same examination, must accompany his proper application and fee by a petition signed by twenty-five legal voters living in the city, county, or precinct where the applicant desires to practise. If he pass a satisfactory examination, and on the same footing as the graduate, he shall receive a certificate, but cannot enjoy the same privileges as the graduate in using a sign or card showing that he is a physician or surgeon, but can only advertise as a licensed non-graduate practitioner of medicine.

The question has been raised, Can the person receiving a license to practise obstetrics practise medicine as a non-graduate? This has already been decided in the negative. The intent of the law is that a license to practise obstetrics does not enable the holder of such license to come under the clause for the non graduate. One, to practise under the non-graduate clause, must be known to have been actually engaged in not only the practice of obstetrics, but the general practice of medicine as well, for a period of five years prior to the passage of the bill. Hence the license to practise obstetrics applies only to obstetrics.

The examinations are conducted wholly or partially in writing, upon the different branches of medicine and surgery. The examinations are for all alike, except in materia medica, practise of medicine, and therapeutics, where the examination is in harmony with the teachings of the school selected by the candidate. The percentage necessary to pass is seventy-five, and the certificate must be signed by each member of the Board. Up to date there have been one hundred and eighty-nine licenses issued to graduates of the different medical schools, and twenty-five to non-graduates, five of whom had passed a rigid examination under the old law.

There are known to be some fifty throughout the Territory who have not complied with the law, all of whom will be reached in the due course of time, and suffer the penalties provided for.

FRANKLIN A. MEACHAM, M.D.

SALT LAKE CITY, UTAH, April 14, 1894.

Medical Items.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 5, 1894.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	6	1
Scarlet fever	164	19
Cerebro-spinal meningitis	5	12
Measles	263	16
Diphtheria	210	50
Small-pox	19	4
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

A Hospital for Lepers, with a laboratory for the study of leprosy, has been established at Rio de Janeiro. Dr. Wolf Havelburg, a German physician, who for the last twelve years has practised in Brazil, has been appointed director.

Thyroid Extract is getting to be a cure-all. Mr. J. D. Menzies finds it useful in eczema and as an external application in ulcers.

Original Lectures.

NON NOCERE.[1]

By A. JACOBI, M.D.,

NEW YORK

I understood that the audience in the General Sessions, consisting of all classes both of medical men and the cultured lay public, was to be entertained with the discussion of subjects, if possible, intelligible to all. Happily, of these there are a great many; for, indeed, the most humane of all the arts is, at the same time, the most human. It is mainly, however, the great specialists in our science that always find topics which, because of their intimate connections with moral, political, and social questions, are interesting to every man and woman of education and culture.

I, Mr. President, am perhaps not so fortunately situated; though I am interested in all of them, I cannot boast of great discoveries in chemistry, bacteriology, or such branches of medical science as are pre-eminently, and sometimes too exclusively, called exact by their adepts and experts. My home has not so much been in laboratories, as on the teacher's platform, and in the sick chamber, the hospital, and the councils of my profession. My life-work has been directed by something like the dictum of Paracelsus, that "true art is not so much revealed by knowing as by acting." Thus I have the honor of addressing you from the stand-point of the practitioner, firmly believing that in medicine, as represented in this Congress, every special research contributed to the general stock of knowledge does not become humanitarian, sacred, ay, medical, before it can be made subservient either to the prevention or the cure of disease. That principle was uppermost in the minds of the framers of these international medical congresses. From that point of view they ordained that special researches should be communicated in their sections, and that all the latter should be held organically together, like the branches of a tree, or the organs of a system, by the binding power of general meetings. If it were not for that, international special societies would fitly take the place of international medical congresses, and we should have twenty-one sciences in place of the one undivided and indivisible medicine.

It is for that reason that our main anxiety must be, under the heading of "Non nocere," that "nil detrimenti respublica capiat." The congresses must remain what they were intended to be, an assembly for scientific, though also for social, purposes, of delegates of great institutions and corporations, of the leaders in general medicine and in its specialties, and of medical men all over the globe whose interests are devoted to science, in their capacity either as teachers and contributors, or as faithful practitioners. All of you, however, who are leaders in the profession and its councils, may you never forget that, as soon as the scientific concerns cease to prevail over the social, as soon as thousands flock together for the enjoyment of entertainments, excursions, and festivities only, or principally, just as soon will the soul escape out of this body medical, and its constituents will be severed. I trust that in all meetings wisdom and moderation will combine to the end contemplated by the founders of our congresses. Do not forget that these congresses are among the intellectual powers of the earth, and that we are responsible to the world for maintaining them in their integrity. From time to time we shall then have the elevating spectacle of thousands of medical men from all parts of the world, and speaking a dozen different languages, convene at the same call and for the same purpose, moved by the same instincts and interests, the great and the lowly, the old and the young, brethren on the same moral and scientific platform, if not of equality, still of fraternity and solidarity.

Still, I set out to speak from the stand-point of the practitioner. The critical physician of the last decade or two has seen wondrous changes. His numbers may have increased somewhat, absolutely, but they have decreased, relatively. In large cities the thorough, all-around, general practitioner is becoming scarce. Now and then he is expected to be but the city directory, or the agent for the specialists in brain and nerves, in kidneys and appurtenances, in uterus and appendages, in skin and corns, in heart and lungs, in stomach, throat, nose, eyes, ears, and what not. It will be very difficult to stem the current, for, indeed, the evolution of specialties, both in science and practice, is spontaneous and legitimate. But the waters left their bed long ago. The tendency of the time is mercenary, the medical man is still a man and but human, and many a one is very, very young, and expects to make a great reputation and an easy living out of very little mental capital, and out of a little manual dexterity, to the neglect of general medicine. "Ein Theilchen hat er in der Hand, fehlt leider nur das geistige Band." He forgets, or never knew, that the great specialistic work is performed by men possessing extensive general knowledge and previous practical training. He does not know or feel that with limiting his knowledge, and running after riches and reputation, he has already encroached upon his morals, and lowered the dignity of himself and of the profession. A young medical man who runs off into a specialty, honestly believing that a human organ can be studied and treated separately, like the wheel of a watch, has not intellect enough to be a physician, and ought to have been discouraged from entering the ranks. He who undertakes it from mercenary motives ought to be frowned down, and told that his tendencies and faculties belong to the places where they sell their wares and souls for lucre, and call it business, not a sacred vocation. You know it is but too true that, while science has taken wings and basked in the brilliant sunshine of rapidly increasing knowledge, the status and the tone of the profession have reason to despond over its restraining clogs. You, who are teachers and leaders in medicine, cannot alter the universal signature of the century; but what you can do is by your teaching to prove the absolute and indestructible dependence upon each other of each organ and the organism, and the logical impossibility of intelligently and scientifically treating a special organ without a closer acquaintance with the body than is obtainable by a four-years' study of medicine and a three-months' special instruction by a teacher who is no better than his pupil. Many a young man sins because he knows no better, and was not told. If the teachers of medicine, if the great professors of specialties in the schools of learning, neglect the duty of teaching from their platforms the morals as well as the science and art of medicine, it is they from whom comes the harm. Moreover, the med-

[1] Address delivered before the Eleventh International Congress at Rome, Italy, in its General Session of April 4, 1894.

ical practitioners, by favoring, as they in their modesty are apt to do, in every possible case, the specialist, and the very existence of the specialists in large numbers and beyond need, have tempted the public into thinking less of medicine and medical men, and more of mere handicraft. That is why the physician has gradually lost his dignified position in large communities. It is in the country, where he still is, in his own person, the sole representative both of his science and his calling, that he is still esteemed at his full value.

This, however, is not the only way in which the medical men of every country have injured themselves and their calling. As they have overloaded their ship with the maintenance of uncalled-for numbers of self made specialists, so they have submitted to the invasion of their lines by the manufacturer of drugs and artificial foods. If the countries be overrun with proprietary and quack medicines and foods, it is to a great extent the fault of the doctors, even those highest in rank. They will accept and praise, and certify to, the merchandises of the venders—I am afraid some of you carry them in your own pockets this moment—open and strengthen the market for them, and thus educate their public into attending and drugging themselves. If there is to be a pharmaceutical gospel, it ought to be for all of us the national Pharmacopœias.

Still another harm comes to the profession from its own members. Through anxiety to do good, and through prematurely jumping at conclusions from a newly discovered fact, we are liable to promise too much, and inadvertently run after fads. *Quod cupimus et credimus libenter.* We promise to extinguish tuberculosis and to cure cholera. The phantasm disappears, and what remains is sneer and ridicule. We pretend to exterminate senility, and those who have to dig graves laugh at us for our pains.

The origin and source of all such harmful mistakes lie in the conscious or unconscious tendency to help and to heal, and in the fact that the practical perfectibility of all medical sciences depends on the good they can do. The greediness with which the modern products of organic chemistry are sought for in the markets of the world by anxious physicians, the great many errors committed in administering injurious doses which—I will only refer to the modern antipyretics with their after affects, debility, collapse, lividity, cyanosis, depression, subnormal temperature, urticaria, salivation, hyperidrosis, etc. — find their explanation in the numberless cases of aches and woes requiring mitigation. But they also lead to the reproach, which is as old as medical practice, that the doctor is killing his patient, not only as Dryden says of the apothecaries in behalf of the warring doctors of London :

> " From random files a recipe they take
> And many deaths with *one* prescription make,"

but with the large number of his medicines and mediæval theriacs.

We all agree not only that over-dosing is wrong and harmful, but also that it is being practised. To give mercury to salivation ; salines until the rest of soluble albumin and salts is gone ; digitalis until heart and pulse are below danger line ; belladonna until the throat is as hard as a gridiron ; quinine until you get deaf ; iron until gastric catarrh and constipation destroy what is left of health ; to burn noses for everything in the line of ailment that may befall the flesh ; to cut the cervix uteri for sterility and endometritis ; to sew up the cervix uteri for sterility and endometritis ; to cauterize and otherwise handle the problematic ulcerations of the uterus for sterility and endometritis ; to introduce glycerol tampons for sterility and endometritis ; are abominations to the minds of well-meaning physicians. Still they are being done, and will continue to be done until knowledge increases, judgment improves, the mercenary spirit disappears from our ranks, and perhaps the public refuses to submit. *Non noceatis.*

But if over-dosing and over-operating be wrong, and sometimes criminal, is it less wrong to under-dose and under-operate ? Indeed that is done, I am sorry to say, to at least as dangerous degree. If you were to stand by a child's bedside strangled by a diphtheritic laryngitis, without resorting to intubation or tracheotomy, would you be made less culpable by relying on some theory of your own ?

It is not enough to avoid legal responsibility, the civil law is mostly on your side—our law-book is the history of our art and the dictates of our heart. Both say that the so-called expectant treatment has done, and is daily doing, more harm than over-dosing. Our sins are those of omission as well as of commission. A whooping-cough leading to broncho-pneumonia, pulmonary hemorrhage, or convulsion in the fifth or sixth week, while it might have been mitigated or checked before, is an arraignment of the doctor. The self-limited eruptive fevers, measles, scarlatina, typhoid, each of them liable to lead to myocardial changes, heart failure, and death, or to mental disturbance, which were not actively treated in time by absolute rest, reduction of heat, and moderate or vigorous early stimulation ; the pneumonia which, when delirium, cyanosis, and dilatation of the right heart became urgent dangers, was not relieved by a venesection ; the protracted and hesitating convalescence, with its anæmia and flagging pulse, which was not supported by heart tonics, not " pro re nata," for res was " nata " already, before it was too late forever, are, and must be for life, loads on the practitioner's conscience. Sophocles says (Aias 581) :

> οὐ πρὸς ἰατροῦ σοφοῦ
> θρηνεῖν ἐπῳδὰς πρὸς τομῶντι πήματι.

" No bright physician mourns plaintively over a case where he ought at once to use the knife." Decision must not be difficult, in spite of Hippocrates (ἡ κρίσις χαλεπή), for ὁ καιρὸς ὀξύς, the favorable time is fleeting. Nor hover over official " maximum doses " in cases where one of the scales contains your anxiety for your own personal safety and lawful righteousness, and the life of a human being is held in the other. Indeed the maximum doses of the Pharmacopœias often appear to be established for the still less than average person who fears more for himself than for his patient.

Parallel to over- and under-dosing, run over- and under-feeding. The latter requires no discussion here, the former I shall refer to only in connection with small infants, for the subject could not be exhausted in ten lectures. They require much food because they have not only to reproduce but to grow. When they take beyond need, one of two things must occur ; for no surplus can pass the alimentary tract any length of time without evil results. Either a surplus material is gradually accumulated in the organs and will lead to disease, or no complete digestion takes place, and then all forms of gastritis, enteritis, or auto infection will develop. I shall only dwell upon two articles which have taken an improper hold on the imagination of medical men, and have almost been raised into subjects of superstitious veneration. The use of milk-sugar in place of cane-sugar in children's food, to any extent beyond what there is in cow's milk, or its exclusive employment, is a source of acid gastric catarrh which afterward requires medicinal correction ; it is transformed into lactic acid beyond need, and proves a detriment to the full conviction of all those who will give the subject proper attention. Thoughtful experience is as valuable an objective addition to our knowledge as a mere chemical or physiological theory.

Next in order is sterilized cow's milk, on which hundreds of thousands of babies are now being fed to the exclusion of everything else. Nobody would teach nowadays the feeding on unchanged or unmixed cow's milk to babies as a proper course to take—as a substitute for mother's milk. But sterilized milk has been looked up to as an object of faith, and treated as a pope among foods, infallible. To feed babies exclusively on sterilized

milk has become the rage since it was recommended by gentlemen of the highest possible standing in science, but, as far as I know, little conversant with the art of treating well and sick infants. I speak so bluntly because I love babies, one and all. Sterilized milk—pasteurized is inferior to it—is superior to unchanged cow's milk, but it is cow's milk still, and not human. Of seven cases, observed this winter, of infant scurvy—a nutritive disorder as far as we can make out—there were three that had been fed, two *exclusively*, one for several months, on sterilized cow's milk.

Mr. President, from the consideration of dangers incurred by the profession through its own fault, I gradually glided into the discussion of injuries inflicted upon the well or sick. That was my main object, and I shall now continue to do so. But you will bear with me when I say just here that what I can bring must be examples only. No book could ever exhaust the subject. These examples will be taken from infant life exclusively. What I mean to discuss before you, will be the three following subjects:

1. A temporary arrest of development, under the heading of *congenital constipation*, and its injurious treatment.

2. The harm done by *certain modes of local treatment in diphtheria*, and on sins of omission in its management.

3. The uselessness and *harmfulness of operative interference with idiocy and with microcephalus*.

These few I selected for your consideration, premising at once that, after having claimed that science finds its highest glory, ay, its apotheosis, in serving mankind, so my address shall try to convey some useful lessons.

Part of the dangers I propose to discuss are congenital, and either of fœtal origin or acquired during birth.

The path of the newly-born is replete with dangers. Bright sunlight beams over ocean and shore after a perilous hurricane, and may meet either a happy landscape or wrecks of ship and man. So the upheaval in a woman's life, with its wonders and terrors, may terminate either in unequivocal felicity or in continued danger. Such a one is the asphyxia of the newly-born, either brief or long; so much the graver the longer; that which occurs after head presentation, or dates from intra uterine inspiration, or depends on protracted pelvic pressure, or is complicated with injury done by forceps or with a spontaneous or traumatic internal kephalhæmatoma, is the worst in its results. Langdon Down elicited the history of forceps application in three per cent. of his idiots; Mitchell details the cases of 494 idiots, 57 of whom had a history of birth after a labor of more than thirty-six hours, 22 that of forceps, 29 of asphyxia. In a large number of cases, four or six every year, of idiots presented at the policlinic of the College of Physicians and Surgeons in New York and elsewhere, after having exhausted every other source of idiocy or mental hebetude, often complicated with peripherous physical symptoms, I am forced back to the probable diagnosis of asphyxia, which then is corroborated by the history of the case. Thus it is that the responsibility of the obstetrician is a very grave one. The future mental welfare of a newly-born may depend on a few seconds more or less of the asphyctic condition. He must allow nothing to interfere between him and the asphyctic baby; not even I should say, a maternal hemorrhage. But now, while he is trying to relieve suspended animation, let him do no harm. There are good methods of resuscitation, some of them very good, provided the tongue is kept well forward. What I am anxious about is to warn against what I have often seen resorted to, the forcible inflation of the lungs through a catheter introduced into the larynx. Though this lies high and appears very accessible, the operation is not always quickly done, time is lost, and the attempt at regaining it has resulted in interstitial emphysema and tearing of lung tissue, to my own knowledge. Air in the pericardium and pneumothorax have been reported. What I am still more afraid of than these accidents is the abuse of the electrical current. Babies will be saved by it, babies will die of it. The interrupted current, to produce satisfactory inspiration, must act a mere second only. While one electrode remains stationary the other must be applied, for a single instant only, as many times a minute as you mean to have respirations. To leave the current at work for a longer time means over-stimulation and sudden death in the asphyctic newly-born, as it does, in later life, in the (fortunately rare) cases of diphtheritic paralysis of the respiratory muscles.

Omitting, for the time is short, daily dangers produced by, and leading to, frequent grave mistakes—among them I think of septic infection through maternal secretions; through aspiration of decomposed liquor amnii; through the umbilical stump and fungi; through abrasions of the skin by forceps; by the hands of the obstetrician or the nurse; by hot bathing; by bursting pemphigus; through the eroded or gangrenous mucous membrane of the mouth and alveolar processes, produced by violent procedures of washing; through external wounds such as circumcision; through dressings, sponges, and scissors—omitting also to speak of the immediate dangers of the narrowness of the nasal channels, depending either on congenital contraction or on early catarrh with all its varied consequences—I now turn, Mr. President, to a subject in which I always was greatly interested for its practical importance, and beg of you first to listen to a tale.

A generation ago I had under my care a newly-born, who began to vomit the day after birth, and discharged no meconium. There was an anus and a rectum, which were freely and often injected during the course of several days, with no effect. The vomiting continued, tympanites set in, meconium was brought up, the abdominal veins became dilated, there was fever. Littré's operation was performed, the colon found and incised, and the baby died of peritonitis some days after. The autopsy revealed the following condition:

Below the point of incision lay the colon, turned three times upon itself; three flexures covered each other in such a manner that the subjacent one was always about one half inch longer than the one above it; the lowest of the three was crowded down into the pelvis, entirely compressed and contracted, and contained nothing but a little hardened mucus. The middle flexure contained the same mucus, and no meconium. The upper one was filled with meconium as far as the contracted lumen of the bowel would allow, and its outer left portion was the only one which seemed dilated (before the operation) by gas, and by the meconium crowding down from above. The inferior flexure reached beyond the median line, stretched upward to near the spina anterior superior of the right side, and from there the intestine turned back in an acute angle into the pelvic cavity, doubled upon itself, reached the median line on the right of the empty bladder, and terminated as rectum in its normal place. The distance from the point of incision in the left hypogastrium to the anus amounted to thirty-five centimetres. The ascending colon was of normal length. The transverse colon was not in its normal position, but stretched out directly to the left spina anterior superior, diagonally, in almost a straight line, formed an acute angle with the upper curvature described before, and gave rise to the pouch I found dilated before and during the operation.

Thus, there was a mechanical obstruction, brought about by the abnormally long descending colon, a condition upon which I look as an arrest of development, inasmuch as its relation to the length of the ascending and transverse colon agrees with their fœtal condition in the last part of utero gestation. By the diagonal situation of the transverse colon, which formed an acute angle with what ought to have been the descending colon; by the mutual compression of the bowels; by its own numerous flexures; by the narrowness of the pelvis of the new born, which became still more marked by the filling up of the bladder; by the infant's crying, which crowded the thoracic and abdominal contents down

upon the intestines; and by the tract filling up with food, fæces, air, and gas, a virtual imperforation of the gut was accomplished.

A brief time after, in the practice of a colleague, there occurred a similar case. A full-term child, no rectal discharge, vomiting, examination with finger and bougie, frequent injections of as large quantities of warm water as the gut would hold, the proposal of Littré's operation, which was refused, and finally, toward the end of the third day, meconium *per vias naturales*. I have seen more such cases since, but never made the same mistakes, for gradually I learned that my mishaps resulted from my ignorance of the fact that what appeared to me extraordinary was indeed but an excessive degree of a more or less normal condition. The ascending colon, after having been formed about the middle of utero-gestation, is quite short in the newly-born, so is the tranverse colon. As, however, the whole length of the colon is considerable, indeed equals three times the length of the mature fœtus, the surplus must be found in the descending colon, and mainly in the sigmoid flexure. This occurs in 25 out of 100 cases of newly-born children. It is found, similarly to what I described in my unfortunate case, bent upon itself in several flexures, crowded out of the narrow pelvis, and frequently, in more than twenty-five per cent. of all the cases, extending beyond the median line of the body, not as an anomaly (according to Cruveilhier and Sappey), not in the majority of cases, as Hugnier claimed, who went so far as to operate for imperforate rectum on the right side of the pelvis; but in a sufficient number of cases; and is important enough to attract our attention for a different reason, viz: A fair number of infants of normal size and weight, and fed on healthy breast milk, suffer from constipation from the first day. There are those who never have a spontaneous discharge; those whose fæces form in hard, round balls of different sizes, unable to pass the sphincter; some who cannot be relieved except by mechanically emptying the rectum. Such cases I have seen by the hundred, and described as *congenital constipation*. It is easy to handle when understood. If we have learned what is the actual fact, that the normal relation of the different parts of the colon may be expected to establish itself toward the sixth or seventh year, we shall have patience. In most cases one or two daily enemata suffice to empty the gut. They must be continued year after year, until the normal end of the anomalous condition will have been reached. Purgative drugs are rarely required—indeed, they are mostly contra-indicated, and when given will do harm. They result in over-stimulation; and paralysis, with more costiveness, is a secondary result. I have seen, as the outgrowth of this congenital constipation, many instances of ulceration, of fetid diarrhœa, of septic auto-infection, of fevers sailing through months under the flag of malaria and continued fever. These are the cases in which the practitioner with knowledge enough, and sufficient intelligence and tact to individualize, will find the occasional indications to regulate the diet, to administer, in rare instances only, a purgative drug; to insist as a rule, however, upon the avoidance of medicines and the administration of regular enemata, and *non nocere*.

Allow me now, Mr. President, to pass to a subject which never appears trite, though its literature fill a library. I offer no apology for briefly considering what I consider harmful mistakes in the treatment of one of the most calamitous scourges of our race.

In diphtheria one of the dangers is suffocation. That can be easily recognized, and the indications for intubation or tracheotomy, repeated fumigations with ten or fifteen grains of calomel, and for steam, are readily found. The second great danger is from exhaustion and heart failure, which is not merely functional but organic. It is always to be feared, for we all know that apparently mild cases may thus perish. The indication, then, is to save and stimulate nerve strength by alcoholic beverages in large doses, and otherwise. The third great danger is sepsis, which is not to be feared to an equal degree in all cases, for diphtheria confined to the tonsils, with their large amount of fibrous tissues surrounding them, and with their scanty communication with the lymph system, is not liable to produce sepsis, and thereby to terminate fatally. The fourth great danger, in the worst forms of diphtheria, is the over officious and directly detrimental exertion of the attending physician in behalf of local treatment.

It is true, where the diphtheritic pseudo-membrane is within reach, it ought to be either destroyed or disinfected. This is not the place to discuss the methods and the remedies. But we must never forget, first, that only a small part of the pharynx is directly accessible to such treatment, and that it is only one class of patients who can be subjected to it. In order to be effective the application must be thorough. None but adults or large children, and of them only a small number, will submit to opening their mouth and having applications made. It is that very class of patients only who can be induced to gargle with anything like success, though indeed, gargling will reach only the oral cavity down to the anterior pillars of the soft palate. Smaller children will object, will defend themselves, will struggle. It takes many a good minute to force open the mouth; meanwhile, the patient is in excitement, and perspiration, he screams, and fights, and exhausts his strength. You may, however, succeed in forcing the jaws; then begins the practice of making applications, of swabbing, of scratching off the pseudo-membrane, of cauterizing, of burning. The struggling child will prevent you from limiting your application to the diseased surface. You cannot help injuring the neighboring epithelium; thus, the process will spread; instead of doing good, you have done harm. No application, indeed, can do as much good as the struggling of the frightened child proves destructive. Even the intervals between the medical assaults are no period of rest to the tortured baby, whose fears result in constant mental and physical trepidation. I have seen them dying in defending themselves against the attempted violence, leaving doctor and nurse victorious on the battle-field. It is incredible, but it is true, that more than one has recommended the use, after forcibly separating the jaws, of the electro-cautery or the thermo cautery on the throat of the baby. It is incredible, for you are aware that the offenders cannot have been, or ought not to be, ignorant of the fact that what they can reach with their instruments is but very little besides the tonsil, and they might have known that the tonsils are not apt to favor the invasion of general sepsis. Why, then, insist upon these cruel and brutal exertions, most of which are discovered and advised by men possessed of a schematic knowledge of a pathological process, which leads them to kill their patients while trying to destroy a bacillus? *le sujet est mort, mais il est mort guéri*. There is no excuse for them, for there are a great many ways in which an antiseptic treatment of the fauces can be carried out, by the frequent administration, both with internal and local effect, of mild doses of medicines, such as chloride of iron and bichloride of mercury.

Again I emphasize the fact, so often forgotten, that diphtheria, not to speak of the larynx, is mostly and almost exclusively dangerous when located in the nose and naso-pharynx. When the blood-vessels ooze slightly the toxine may be immediately absorbed into the blood, circumventing the lymph circulation altogether; or there are more perceptible diphtheritic membranes, either thin and macerating, or thick and obstructive, either odorless or fetid. The pseudo-membranes swarm with bacilli and toxine, with streptococci and staphylococci, and lead to immense tumefaction between the ears and clavicles, to the formation of multiple abscesses, to hemorrhages, to sepsis. All of these forms of nasal diphtheria require immediate, persistent, and efficient local treatment, for it is safe to say that every case of nasal diphtheria has a tendency to terminate fatally. Every procrastination is a death sentence. The local treatment is to consist in

cleansing and disinfecting. In the bad cases, in which the nares are clogged with pseudo-membrane, the cleansing and disinfecting is to be preceded by forcing a passage through the nares with a probe covered with wadding and dipped in carbolic acid. Particularly is this indication urgent when there is sopor, which owes its origin partly to the difficulty of respiration, and partly to the septic condition. Again, I must abstain from alluding to methods and to remedies, for I proposed to say, not so much what is to be done, but what is to be avoided. Still, not to properly propose the proper thing is *nocere*, is committing a direct injury. Therefore, I will say briefly that in making local applications it is important that they should be made often, every half, one, and two hours, and that the whole diseased surface should be touched. *Si duo faciunt idem non est idem.* Your personal supervision and interference is required, for one day, two days turn the scales. Ointments are not available in the average cases, where the whole naso-pharynx is the seat of the affection. The atomizer will seldom convey a sufficient amount of liquid into the cavities to be of much use. A spoon or small feeding-cup, the nozzle of which is narrow enough to enter the nose, will do fairly well, and will allow the introduction of liquids into the nares in small or large amounts, all of which will enter the throat, and be either swallowed or flow out of the mouth. The irrigator is liable by undue pressure, which cannot always be well measured, to injure the ear. It is true that this cannot take place very readily as long as the whole naso-pharynx is covered with pseudo membrane, but this will not always remain, and then there is a possibility of the injection entering the middle ear. This will take place the more readily the younger the infant, because the pharyngeal orifice of the Eustachian tube is relatively larger and much more funnel like in the very young than in advanced age. I prefer a small glass syringe with a conical nozzle of soft rubber. It will close up the nostril, the pressure can always be well measured and modified, and it is effective. The injections must be made in the recumbent or semi-recumbent position, frequently. On no condition must a child be taken out of bed for the purpose of having the nares washed and disinfected. I know of many cases in which the patient has thus died through being taken up by either nurse or doctor. There you have at once grave sins both of omission and of commission. I follow it up with one of omission, which is just as bad, because it is just as fatal. As I have personally seen thousands of innocents die of diphtheria, thousands of them in the course of thirty-six laborious years, therefore, with trembling heart, I know whereof I speak; and still they are dying by the hundred thousand all over the globe, and that is why I preach my old sermons.

Non nocere. Do not harm, and permit no harm.

Cervical lymphadenitis resulting from nasal diphtheria, no matter whether it is the result of bacilli or equally septic and fatal streptococci, must be treated persistently and effectively. This treatment must be preventive and curative. The preventive treatment consists in the frequent nasal injections described above. They will reduce the immense tumefactions, partly glandular, partly peri glandular, which extend often from ear to clavicle, within twelve hours. When large tumefaction has taken place, tincture of iodine and mercurial ointments are useless. Ice externally is rational, but it is useless as long as the infection is not stopped. I have, in a number of instances, injected iodoform, in ether, into the swelled mass. It is too painful and too inefficacious, and does not pay for the agitation, the anguish, and the exhaustion of the unhappy baby. So, indeed, there is no remedy besides the preventive measures, except in long and deep incisions into the immense mass. Do not wait for fluctuation, or even semi-fluctuation, for a great deal of the swelling is inside the fascia. Abscesses, when they form, are seldom large. The formidable swelling consists mainly of necrotic tissue, which ought to be laid open as soon as possible and disinfected. The incision must be a long and deep one—in most cases, from ear to clavicle. The disinfection of the wound may be obtained by subnitrate of bismuth, by tincture of iodine, and iodoform or other antiseptic gauze. No carbolic acid can be used for disinfection, because of its tendency to give rise to hemorrhages. When hemorrhage takes place, it is apt to stop under pressure with antiseptic gauze, but sometimes, large blood vessels having been eroded, the hemorrhages are very copious. In such cases the actual cautery, acupressure, sometimes the ligature of blood-vessels, has to be resorted to. Avoid perchloride of iron and subsulphate of iron, for they give rise to a thick coagulated scab, under which septic absorption is apt to take place.

In connection with this subject of diphtheria, I may be permitted to allude to a remedy which, while having a healing and protecting effect in catarrhal conditions of the oral cavity, never had any right to be puffed up into being a remedy for diphtheria. Large doses, however, have been recommended and given, with the result that many years before I published (1876) cases of fatal poisoning by potassic chlorate in Gerhardt's "Handbuch der Kinderheilkunde," I had seen such cases in fair numbers. Both nephritis and methæmoglobinuria, as found by Marchand, were the effect of its administration. Numbers of such cases have been reported since, and still I have read but lately of the same big doses of the same poison praised in this very dread malady. Are we never to learn from our predecessors? Is our experience of so little consequence that its history counts for nothing and must not be consulted? Is diphtheria not dangerous enough by itself? and must it be punished by fatal doses of ours?

The last subject I dare to discuss before you is that of linear craniotomy, *craniotomie à lambeaux*, and circular craniotomy. The two former have been introduced by Lannelongue, who, in 1891, published twenty five cases of "Enfants arriérés et jeunes sujets présentant, avec ou sans crises épileptiformes, des troubles moteurs ou psychiques." The results he claimed, not only as far as recovery from the operation was concerned, but also as to the improvement in mind which was said to have taken place in a remarkably short time, were so striking and novel that physicians began to hope, surgeons to glory—and the idiotic children? Let us see.

When the brains of operative surgeons were taken with the *furor operandi* on the brains of luckless children, the war-cry was: microcephalus and idiocy. By many the two were identified. Nothing henceforth was required but to open the heads in order to admit light. The literature on the subject having been quite extensive all over Europe, the American facts I intend to give you will require but a brief introduction.

Which are the underlying conditions of idiocy? I recall to your minds only the following records of autopsies and anatomical examinations both of the coarser or finer tissues: Chronic encephalitis (Jeanneret, Stark, Mierzejewski), either diffuse or circumscribed, frequently syphilitic; diffuse (syphilitic) disease of the blood-vessels (Popoff); arrest of vascular development in the cortex (Luys); inequality of the hemispheres; inequality of the peripherous cortical layer on the two sides; defect of the third frontal convolution and island of Reil; meningo-encephalitis with thickening and adhesion of pia and brain such as may occur after forceps or other trauma; kephalhæmatoma internum, spontaneous hemorrhages; embolism from heart disease; thrombosis from cholera infantum, followed by destruction of cerebral cells and atrophy of cortex. This condition was found in 21 cases out of a total of 343 collected by Starr. He further reports: Maldevelopment and apparent atrophic condition of the brain-structure of the hemispheres, chiefly cortical, the cells resembling those of a new-born child, but with no apparent gross defects in the brain, 32 cases; atrophic or hyperplastic sclerosis, congenital or post-natal, 97 cases; atrophy by softening produced by embolism or thrombosis, and limited to certain arterial districts, 23;

arrests of development such as porencephaly, 132 (frequently in a thin cranium); cysts which produced atrophy by pressure, or were associated with the atrophy due to the original lesion, 14; hemorrhages which were discernible by the remains of a clot, or by the hæmatin staining of a cyst of the pia or of sclerotic tissue, 18.

Finally there is among the causes of idiocy hydrocephalus, microcephalus with or without micromyelus, or other changes in the spinal cord, mainly of the pyramidal tracts;[1] and lastly, premature ossification of the fontanelles and sutures.

Meningo-encephalitis in some form or other is very common. Here belongs one of Lannelongue's early cases described by Bourneville. It was operated June 22, 1890, was kept in the hospital to February, 1891, was then carefully nursed and trained, but got no better, and finally died of broncho pneumonia. What did the autopsy reveal? Pachy- and lepto meningitis, normal sutures, wormian bodies between them, and a thin and transparent skull.

If we be told that the operation is made for microcephalus—indeed, many of the histories intrusted to me exhibit that diagnosis though but few measurements be given (in one of which the head had a circumference of 50 ctm. [20 inches])—what does it mean? Which are the causes of small headedness? Is it always premature ossification? Very far from it; the copious literature of microcephalus proves the contrary. Taquet reports 26 skulls of idiots, none of them ossified. Bourneville demonstrated 12, all of them with persistent sutures, 3 even with pathological disconnections. With me it is the rule to see microcephalus with open sutures. While the anterior fontanelle need not be large, the sagittal sutures mainly, but also the others, are open and remain so for years—four, five years, and more. If, finally, the bones coalesce, let me ask the question, is there a sound man who can believe or hope that the linear or circular reopening of the skull will encourage brain growth which did not exist while the sutures were still patent?

Now, premature ossification, in our sense, does not mean absolute absence of the sutures, which is almost never seen. Vrolik's case of a boy of seven, and Cruveilhier's of a child of a year and a half, without any discernible sutures, are exceptional. Nor is it of any importance to know that, according to Huschke, the cranium does grow up to the sixtieth year, or that Pommerel puts synostosis between the forty-first and fifty-first year, or Sappey complete obliteration of the sutures beyond the eightieth. What concerns us is to know that the rapid growth of the brain is impeded normally, if at all, by a virtual closure of the sutures about the fifteenth month of life, and that, according to the period of this closure, the intellect is either but little or much impaired, or that the most serious motory, sensitive, and sensory disturbances are brought about by it. Between a slight impairment of mind and complete idiocy every possible degree and manifestation is met with. Virchow's old dictum, that cerebral functions may depend on size and symmetry of cranium and brain, still holds good. He never said there was no other cause of the disturbed cerebral equilibrium, and a recent writer who gloats over his own assertion that this teaching of Virchow's has been put to rest, lost his own equilibrium in his critical effort.

The nature of premature ossification can be best studied in such cases as exhibit that anomaly to a slight degree only, and symmetrically; namely, where the closure of the cranium takes place, say between the fifth and tenth months of life, instead of the fifteenth. There you have a solid capsule, with deep digital impressions, like those of an adult, and narrow or absent foramina emissaria. The dura mater is firmly attached, rather anæmic, unless a secondary morbid process resulted in hyperæmia; in the same condition is the substance of the brain; it is pale and dense; its convolutions are apt to be flattened, remain in that condition when the dura is cut or bulges out like an elastic mass; the ventricles are narrow and contain but little, if any, liquor. The brain when removed from the cranium is apt to remain hard, and slices of moderate thickness retain their consistency.

This condition of a relative hypertrophy of the brain, or rather, of a normal brain locked up in an abnormal skull, I have met with quite a number of times, before and since I published, in 1857 and 1859, my papers on the etiological and prognostic importance of the premature closure of the fontanelles and sutures of the infantile cranium. A similar case was published by Mauthner in 1857, in the *Oesterr. Zeitsch. f. Kinderheilk.*; but even some of the greatest pædiatrists, such as Rilliet and Barthez, had and have since overlooked the condition. It was only Bouchut who quoted a description of this condition in his manual. This class of children are apt to exhibit a good or fair intellect during their early lives. They smile at the proper time, are robust and apparently healthy, but with that complication every morbid condition is liable to develop dangerous symptoms; a moderate broncho-pneumonia is apt to become complicated with convulsions, and may prove fatal; or, without any apparent complication, there will be slight symptoms of irritation, contractions of the extremities, clonic convulsions, sopor, death. Generally, there are no unilateral symptoms; where they occur, they are rather the result of a convulsion, followed by a local lesion, than of the original compression of the cerebral tissue. As I have met with such cases in large numbers, I always examine the heads of babies affected with any inflammatory or febrile disease. Simple cases, like the following, will be met with: A boy of eleven months was seen November 1, 1857, after having been quite well before. In brief intervals there was fever, vomiting, clonic convulsions, dilated pupils, and death on the sixth day. The head was of fair size, symmetrical. There were six teeth; the first had appeared in the upper jaw. The fontanelles were virtually closed three months previously.

Many cases are of this simple character, but many more are less hopeful. Paralysis, epilepsy, idiocy are met with in those whose crania were closed at birth or soon after, and every possible symptom of paralysis or irritation, unilateral or bilateral, may become visible. Besides, we must not imagine that premature ossification is always of the same character. It is true it depends on a local nutritive or inflammatory disorder of the bone; but it cannot always be known whether this process is localized or complicated. It may be independent of the brain. Zuckerkandl says so, and I know it. It may be complicated with similar affections of the brain, and with premature growth and development of the bones of the face and of the teeth and the rest of the body. Therefore it is that in many cases premature ossification is universal, and the teeth come early, and the upper teeth first. In others the teeth may come at the normal time, or even later, and the bones of the trunk and extremities may by no means be more advanced than normally; also the brain symptoms may be of the most various kinds. Among my cases are the following: In Vanderveer's, the fontanelles closed at nine months; no vision, eyes roll, head not sustained, frequent convulsions, body well developed; idiocy. In Willy Meyer's, anæmia, paralysis of the lower extremities, strabismus; idiocy. In Wyeth's, restlessness, "cataleptic attack," talipes varo equinus, mainly of the left side, left hand slightly flexed, spasms of the internal recti, pupils dilated, jerky movements of arms; idiocy. Now, what is the diagnosis of premature ossification?

The latest writer on the operative treatment of micro-

[1] This connection has often been observed (Aeby, Thiry, Flesch, Anton). In their slow evolution (Hervouet) from the fifth month of uterine life to the completion of the fourth year, many changes are liable to take place. The number of the cells of the anterior horns was found diminished by Hervouet, Steinlechner, Gretschischnikoff, Schottenberg. Other arrests of development are also frequent. Bourneville mentions phimosis, and patent foramen Botalli, ectopy of testicles, and hypospadias. The two latter I met with several times.

cephalus has the following to say in regard to diagnosis: "As changes of the cranium cannot be recognized with certainty, anamnestic points are of the greatest importance. Where the history excludes protracted and difficult labor, the application of forceps, the presence of asphyxia at birth, or cerebral affections and kephalhæmatoma after birth, the symptoms of traumatic epidemic, or endemic meningitis, or the local signs of diffuse or circumscribed encephalo-meningitis, or the motory or sensitive disturbances of porencephaly, all of which may result in deaf-mutism, blindness, paralysis, either general or local, or in local convulsions or contractions—where all these can be excluded, it is permissible to assume the presence of premature ossification, and to perform an operation."

Still many of these symptoms may occur in premature ossification also, the diagnosis of cerebral affections leaving still so much to desire; I know, however, we can do better in the direction of a diagnosis. What I have to propose in that line is old, I know, but for many I am certain it is new, for if it were not, many of the reckless operations on the helpless, unfortunate young ones would not have been performed. In this respect I totally disagree with my famous friend, M. Allen Starr, who asserts that it is at present impossible to determine absolutely the pathological condition present in any given case, without an exploratory operation.

In a great many cases I have succeeded in making the diagnosis with certainty. Some are unmistakable; they

Reported by	Patient.	Age.	Diagnosis and history.	Operation.	Results.
Dr. Charles McBurney.	M. H. (female)	12 yrs	Microceph. since birth. Mentally weak, petit mal, and convulsions.	Nov. 11, 1892	Petit mal not so frequent.
	Same.			Dec. 19, 1892	Attacks as formerly. Feb. 20, 1894, Dr. Starr's report: much improved in many ways.
	W. L. (male)	6 yrs	Microceph. Deficient in mind, unruly, no intelligible speech.	Oct. 6, 1893	April 11th, no change. Feb. 20th, Mrs. Seguin thinks "improvement great and out of proportion to other not operated similar cases."
	F. M. (male)	7½ yrs	Well until 4 years of age. Convulsions, fever, right hemiplegia, aphasia, epilepsy.	March 27, 1893	No improvement.
Dr. Willy Meyer	M. B. (female)	2 yrs	Microceph., oxyc., premature ossification, anæmia, paral. ext. inf., strabismus, idiotic expression. Forceps, strabismus, and insufficient motility of both lower extremities since birth, lately frequent convulsions, general and local (face), head retracted during sleep.	May 8, 1891. Linear craniotomy, little hemorrhage, 9 ctm. long, 2 ctm. wide.	Died May 11th, with high temperature (up to 106°), gritting teeth, sudden cries, and retraction of head.
	J. B. (male	4 yrs	Tumor suspected	June 19, 1891. 12 ctm. long, 3 ctm. wide.	Died after four hours, increasing temperature.
Dr. John A. Wyeth	B. S. (male), N. J.	4 yrs	Skull 50 ctm., epileptic since 4 months, no speech, no hearing.	April 7, 1890	Died after twelve hours, shock.
	I. W. H., Ind.	11 mos.	Font. closed at 4 weeks, restless, "cataleptic attack at 8 months, after which tal. vaso-eq. mainly left, left hand slightly flexed, eyes conv. mov., pupils dilated, dull look, jerky movement of arms, cran. small, pointed."	Jan. 7, 1891. Two long trenches above eyes to occiput, tearing of bone from dura.	Sept. 1893, "triumphant letter" of mother. Jan. 31, 1894, "4 years, but 2 or more behind in mind," speaks a few words.
	R. R., Conn.	14 yrs	Infant small, delicate, sinking spells the first 2 and 3 weeks with cyanosis, feli at 2 years, 6 weeks after convulsive through 2 years, free 5 years, head small, epileptic.	Oct. 20, 1891	Temporarily improved; No improvement (letter of mother).
	F. H. G., Conn.	5 yrs	Microcephalic	Nov., 1891	Died after fourteen hours, shock.
	L. H. G., Me.	22 mos.		Dec. 16, 1891	Died on the sixth day.
	J. O. (female), N. Y.	20 mos.		March 21, 1892	Died on the third day, portion of right par. bone removed.
	H. C. C., N. Y.	4½ yrs		Jan. 4, 1893	No improvement.
	I. F. D., N. Y.	2 yrs		Jan. 4, March 29, May 8, 1891. Portion of both par. and occ. bones near vertex removed.	Feb. 14, 1894, splendid physique, after excitement jerking in sleep, recognition better, knows family, kicks when tied in chair, cannot stand without assistance, does not grasp or hold fast, less rolling eye, not much crying, left hand always closed, hearing good, delighted with music."
Dr. W. W. Keen	M. E. (female)	4 yrs. 7 mos.		Nov. 19, 1890, Feb. 17, 1891.	Recovery. Moderate improvement.
	K. K. (female)	1 yr. 7 mos.		March 12, 1890, Feb. 3, 1891.	Recovery. Moderate improvement.
	I. L. H. (male)	1 yr. 4 mos.		Jan. 16, 1891	Died of sudden heart failure one and one-quarter hour after operation.
	E. S. (female)	3 yrs. 6 mos.		Nov. 7, 1891	Recovery. No improvement.
	L. F. (male)	2 yrs		Oct. 14, 1891, March 16, 1892.	Recovery. No improvement, but slept quietly.
	G. F. C. (male)	3 yrs. 2 mos.		Oct. 20, 1891	Died the same day.
	H. T. (female)	6 yrs. 6 mos.		May 29, 1891	Recovery. Slight improvement.
	P. I. (female)	6 yrs		1891	Died after three hours.
	H. H. (female)	3 yrs. 6 mos.		Nov. 2, 1891	Recovery. No improvement.
	F. S. (female)	3 yrs. 2 mos.		March 15, 1893	Recovery. Slight improvement.
	F. W. (female)	1 yr		April 22, 1892	Died after a week.
	H. T. M. (female)	2 yrs. 6 mos.		April 27, 1893	Died after thirty hours.
	M. D. (female)	3 yrs. 3 mos.		May 29, 1893, June 22, 1893.	Recovery. No improvement, skull as thick as adult's.
	M. D. D. (female)			Sept. 29, 1893	Recovery. History unknown.
Dr. Burney Sachs	Female	4½ yrs	Walked after 2 years, spoke a little in 2 years, two convulsions at 15 months, one at 29 months, more idiotic since, lost speech, irritable, unruly, sleepless. No fontanelles, circumference of head 31 ctm., nose to occipital prominence 30 ctm., binauric 25½ ctm.	Jan. 9, 1891	Died suddenly in three and a half hours after rallying.
	Male	4 yrs	Forceps and asphyxia, some convulsions between first and second year, teething late, walked after 3 years, drags left leg, no speech. Skull small in front 45 ctm., binaur. 28½ ctm., naso-occipital 27½ ctm., right.	Sept. 14, 1891, linear right under ether.	Laughed, stood up in bed, played as never before, otherwise no improvement.
	Same.			Nov. 20, 1891, left, chloroform, more hemorrhage than in first operation.	Unconscious, vomited much. Died eleven hours after operation. Autopsy: skull thick, dense bands of fibrous tissue under opening in skull, sutures obliterated, anterior lobes of both hemispheres very irregular in fissuration, convolutions half size.
	Female	5 yrs	Four convulsions between 15 months and 3½ years, discharge of ear since third month but hearing fair, eyes normal, no intelligible speech, eats the floor, does not call for food or defecation.	Jan. 29, 1891. Trephine, chisel, rongeur, like previous operations.	Died the next afternoon.

are those which were born with their sutures closed, and with early cerebral symptoms of a general and bilateral nature. Still some difficulty may arise about those who are first presented when from one to three years old or older. Indeed there are some of the operative cases in my hands, three and four years old, which are supplied with the notice that the sutures were closed at that time. Indeed they should be, for the time of the normal obliteration is within the first half of the second year of life. Now there are but few parents but can answer the following questions: Was there ever a fontanelle? Was the head ever soft on top and pulsating? How old was the baby when he first smiled? When did he walk or attempt to walk? When did the first tooth come? Was it a lower or upper tooth? Are the teeth strong and healthy, or not? Are the right and left limbs equal in power? If there be twitching or rigor are they more visible on one side than on the other?

The replies to these questions make your diagnosis. The first appearance of teeth in the upper jaw is an almost constant symptom and characteristic (though irregular protrusion of teeth may occur in rachitis). Uncomplicated cases will also stand on their feet early. It appears that in many the whole osseous tissue ossifies at a nearly equal pace. The superior maxilla, however, appears to participate in this general process more than the rest. It is noticeable that these children with premature ossification are generally the first born.

The more irregular the cerebral symptoms, the more unilateral, or confined to one limb or a set of muscles, the greater is the probability of a complication of brain disease with premature ossification. In such cases of older children the history elicited must be positive as to the absence of a fontanelle in the first year.

What are the indications for the operation? Starr says when the condition is one of arrested development of cerebral tissue it may be of service. When the skull is markedly microcephalic from early union of sutures the increased space given to the brain by the operation appears to stimulate its growth and development. It may be performed where medical treatment is inefficient, in hemiplegia, sensory defects, imbecility with or without epilepsy, aphasia, and athetosis. He is also of the opinion that if great caution and little time be used the dangers of the operation can be avoided. European operators go far beyond these indications. One claims to have transformed mania into quiet dementia—a change which is common enough without saw and chisel—by destroying fibres of association (Burkhardt); but while another operates for septic meningitis, recent hemorrhages, and headaches (Horsley), another restricts the surgical interference to abscess, trauma, and tumor (Bourneville).

Lannelongue's first report of 1891 comprised twenty-five cases of linear craniotomy with remarkable results; a great many improvements were said to have taken place in the twenty-four survivals. No such statistics have ever since been submitted; on the contrary, the mishaps of the surgeons of both hemispheres make them appear more fabulous than ever. But the brilliant example was not lost. It was about the time of the tuberculin excitement. Pulmonary tuberculosis and idiocy in all its forms could be eliminated from the surface of the globe by simple means—the millennium was coming.

I hold in my hand, Mr. President, the reports of cases operated upon for so-called idiocy, or for so-called microcephalus, by such American surgeons only as I could reach personally, so as to have their tales verified from their own lips. The cases I command are 3 of Dr. Charles McBurney, of New York, 2 of Dr. Willy Meyer, of New York, 8 of Dr. John A. Wyeth, of New York, 14 of Dr. W. W. Keen, of Philadelphia, 3 of Dr. Barney Sachs, operated upon by Dr. Arpad Gerster, of New York, and 2 of Dr. I. Vanderveer, of Albany, N. Y. On these 33 cases 41 operations were performed. Of 33 there were 14 deaths and 19 recoveries. The deaths did not occur in the very young ones alone, but also in those four, five, and six years of age. Most of them occurred soon after the operation, six within a day. Cause of death is not always given or known, in one it was attributed to the anæsthetic, a number of them developed a very high temperature which was not explained, inasmuch as not even the dura was injured. Many died of shock a few hours after the operation.[1] The final report as to their mental and general condition was as follows: No history obtained, 1; uncertain, 1; no improvement, 7; slight improvement 7; "some," 1; much improvement, 2.

Permit a few more words as to the results of the operation.

Dr. Vanderveer, of Albany, N. Y., reported the case of a girl two years of age. Forceps operation of four hours' duration resulted in extensive lesion of the scalp. Never developed mentally; had as many as twenty-five convulsions daily, with and without vomiting, after the age of three months. Operation October 14, 1893, on the left side of cranium, four and one-half inches long, extending to nearly the lambdoid suture, and one inch wide. Left hospital October 30th. Seventeen short days after that, November 15th, the family physician reports that since November 8th the child did not sleep well, and had returns of the nervous spells or partial convulsions; but before that, ten days after leaving the hospital, the child seemed brighter and took more notice of things around her.

The following case was also reported by Dr. Vanderveer:

Arthur McKee F——, born May 22, 1891. Previous to his birth a miscarriage at six weeks and a still-birth. Mother had albuminuria every time (syphilis?). Teething at nine months. Then the fontanelle was noticed to have closed. Examined July 1, 1892. No vision, eyes roll, head not sustained, body well developed. Convulsions frequent. Operation October 6, 1892, on left side from frontal to occipital bones, four inches long, one wide. November 2d appeared "more natural." Second operation May 19, 1893, on the right side. Examination of the left side of the skull at this time did not give evidence of any great development of the brain, as there was rather a tendency for the dura to sink in than to rise above the surrounding portions of bone. November, 1893, more quiet, does not see, recognizes sound, moves arms and legs, and stands when supported.

Dr. John E. Wyeth reports a case which appears to be one of premature ossification with cerebral complications, though there be no exact measurements. The fontanelles are said to have closed when the child was four weeks old. The operation was performed when the child was eleven months old. January 7, 1891, two long trenches were dug from above the eyes to occipital bones, and joined posteriorly, the bone torn off from the dura and elevated so as to produce a fracture anteriorly. On September, 1893, a "triumphant letter" was received from the mother. On January 31, 1894, however, she writes that the child was now four years of age, but two or more behind in mind. It may be remembered that this is three years after the operation.

Léon Gallez says, in his "La Trépanation du Crâne," p. 417, 1893, of craniotomy that *elle procure le plus souvent une amélioration évidente*. That is an over-estimation. Personal knowledge of the facts he does not claim. Firstly, the mortality of the operations is very great. Secondly, a large number of cases are admitted not to have been benefited at all. Thirdly, when amelioration has been reported, what does it mostly amount to? It would be absurd, theoretically speaking, to deny the power of observation or the veracity of those who report; but who are they in most instances? In the majority of cases they are loving, hoping mothers. Who has not seen to what extent the idiotic child in a family—frequently the first born—is petted, made most of, admired,

[1] According to Akerman the causes of death after the performance of the operation, and depending thereon, were acute sepsis, loss of cerebro-spinal liquor, shock, collapse, fever, acute anæmia, and the anæsthetic employed during the operation. Altogether the deaths amounted to from fifteen to twenty per cent. of all the operations collected and discussed.

and how every ray of mental light is reflected from a magnifying mirror of adoring and anxious scrutiny. Besides, many of the reports are made soon after the operation, and therefore become rather valueless. Moreover, after the performance of that serious operation, made for a special purpose, attention and training are doubled; and progress attained through assiduous training was never questioned even before the times of Edward Seguin. Finally, a difference of from one-half to two years amounts to a great deal in a child of one or two years of age, in the possibility of mental improvement.

A temporary relief, either entire or partial, of epilepsy, does not mean much, for any operation on any part of the body is apt to modify its course.

Altogether, the mortality and the insufficient results in those who survive have exerted a discouraging influence on my surgical friends. What here follows are the opinions of some of them as they were expressed but a short time ago.

In a letter dated June, 1892, when he had operated on twelve cases, Dr. Keen makes the following statement: "I would at present operate on cases under eight years of age, but not over, and in cases with sufficient physical vigor to make recovery probable. I would only operate on one side at a time, but make the incision as long as possible, from the forehead to the occipital bone, and possibly, or even probably, T-shaped by a vertical incision toward the ear. My results have been those of improvement in almost all the cases that survived; an improvement makes the operation worth doing. But do not promise too much intellectually or even physically."[1] In a letter I received from the doctor lately (1894) he says: "The mortality is very high, and in my experience the gain is moderate, but possibly worth the risk."

Dr. Wyeth formulated his experience for me on February 22, 1894, as follows: "My operations were eight.[2] There were three deaths, one dying of hemorrhage on the table, two of shock, of whom one after twelve hours, and one with temperatures of 104° and 105° F., on the fourth day. There are two varieties of microcephalus, one due to premature ossification and consequent compression; and one due intrinsically to deficient brain development. These can be made out by incision through scalp, when the white cartilage lines can be seen in the intercranial sutures. Operation is useless in these cases, unless cyst or tumor be present. In the other cases, temporary improvement at least can be expected." In a letter published in the *Journal of the Arkansas Medical Society*, October, 1893, he says: "The operation is so dangerous that I shall hereafter undertake it only in cases of very marked microcephalus with undoubted symptoms of compression."

In reference to these operations Dr. B. Sachs says he has not advised them since 1891. He regards the danger "extremely great in all young children, the shock and uncontrollable hemorrhage from the scalp and bone being greater than most children are able to stand." And Dr. Arpad Gerster, who performed the operations for Dr. Sachs, expresses himself as follows: "The operation of linear craniotomy is a very serious one in small children, on account of the unavoidable hemorrhage accompanying it. Yet, in view of the otherwise hopeless outlook, I am still willing to undertake it in well-nourished individuals, at the direct request of their parents. As our diagnosis is very unsatisfactory as to the condition of the brain in microcephalus, the operation is often the only test of the presence or absence of cerebral structures which, if present, might develop, if the confinement due to premature ossification of sutures be relieved by craniotomy. On the whole, my standpoint as regards the future of the operation, is not a very cheerful one." Finally, Dr. McBurney is only willing to perform the operation on the responsibility of a medical man in whose judgment and knowledge he has absolute confidence.

Lastly, and unfortunately, what is the result of the operation in reference to the intended enlargement of the cranial cavity? In a letter dated March 11, 1894, Dr. Vanderveer says: "Both Dr. Hun and myself have the impression that the skull has not expanded, but that there is some reason for believing that the resulting cicatrix in the scalp and membranes has caused a diminution rather than an enlargement of the brain." Bourneville finds a narrowing of its interior by thick fibrous bands encroaching upon it in a case the drawing of which he publishes, and the cranium I here present, placed at my disposal by Dr. Burney Sachs, and twice operated upon by Dr. Arpad Gerster, proves the exact condition alluded to by Bourneville. Instead of enlarging the cavity the operation has diminished it. The whole lower aspect of the first craniotomy wound is thickened by about half a centimetre of a newly formed hard tissue; it presses down upon the brain which the operation was expected to relieve. The first operation was performed on September 20, 1891, the second on November 26th. Thus the changes you here perceive are the results of sixty-seven days revengeful action on the part of nature.

After all, Mr. President, that I could contribute to the knowledge of the operative interference with the condition of "enfants arriérés," of idiocy, of microcephalus, it appears that, in the face of so many deaths and so few results, the operation is not promising of good to mankind. The operations thus far performed do not effect what they were intended for, they do not even enlarge the cavity. Wyeth knew that well when he made a circular groove and raised the bone from the dura mater forward, leaving a bridge of one and a half to two inches, which he fractured and allowed to heal. For a similar reason and in a similar manner Dumont,[1] treated a child of fourteen months with epileptoid attacks and strabismus. I am not informed of the condition of the bones or fontanelles. An incision was made from the forehead over sagittal suture until it reached the spina occipitalis externa. Galea and periosteum were severed down to the tubera parietalia. A number of trepanations were made, each of 2.5 ctm. in diameter. Gouge and saw were used so as to connect these openings and render the bone movable. The galea was sutured, no drainage applied, and the wound healed. Two months after the top was still movable and there was no epilepsy, and less strabismus. I am not acquainted with the final outcome. It is not improbable that the extensive denudation of the bone will have bad results in the shape of necrosis. I should rather believe that a circular incision and removal of the galea and periosteum, merely as far as required for a sufficient grooving of the cranium, would be safer.

If any cases be at all amenable to treatment by such an operation, they must be those of uncomplicated premature ossification of the sutures and fontanelles. Such a one appears to have been that described by Akerman. He operated on a child aged sixteen months. Forehead narrow, circumference 40.1 ctm.; mother did not notice a fontanelle. Circumference of head was not changed two and one-half months after the operation, and the angles of the wound had filled up: ten months after the operation circumference was 42 ctm., the usual increase, perhaps a little less, of that age. And the final report, when the child was three years old, was that there were less convulsions than before the operation, and the mother says the child "knows the difference between me and a stranger."

An additional case was published by Dr. I. A. Dibrell, Jr.,[2] of Arkansas. It was that of a girl three years of age. circumference of head 16 inches (40 ctm.), bipar. diam. 4, occipito-frontal, 4⅝ inches. There was "complete ossification of all the sutures and fontanelles." Ten months afterward the operator reports: "I am unable to perceive the least improvement in the child's condition."

Dr. Roswell Park[3] operated on a girl of four years, for premature ossification. No result.

[1] Journal of the Arkansas Medical Society, October, 1893.
[2] The histories Dr. Wyeth was so good as to place at my disposal refer to eight cases, with nine operations.

[1] Corresp. Schweizer ä., 23, 1893.
[2] Journal Arkansas Medical Society, October, 1893.
[3] Medical News, December 2, 1892.

Dr. Willy Meyer's case died two days after the operation, with unexplained high temperatures.

Dr. Wyeth's case was operated on when eleven months of age; when the child was four years of age, the mother admits he was "two or more years behind in mind."

Dr. Vanderveer's child was operated when thirteen, and again when twenty four months old. A year afterward he was "better in some respects."

And that is all there is of it.

The relative impunity of operative interference accomplished by modern asepsis and antisepsis, has developed an undue tendency to, and rashness in, handling the knife. The hands take too frequently the place of brains. Who does not know that the alleged safety in operating tempts some of our skilled operators, and the credulous public, into useless or even contra-indicated procedures? Who is not aware that but too frequently the first principles of diagnosis are not practised before an abdominal wall is opened? Is it enough to know that clean fingernails, and nurses conversant with corrosive sublimate, and disinfected catgut, are almost universal safeguards against immediate fatal termination? Is it sufficient glory to don a white apron and swing a carbolized knife, and is therein a sufficient indication to let daylight into a deformed cranium and on top of a hopelessly defective brain, and to proclaim a success because the victim consented not to die of the assault?

Such rash feats of indiscriminate surgery, if continued, moreover in the presence of fourteen deaths in thirty-three cases, are stains on your hands and sins on your souls. No ocean of soap and water will clean those hands, no power of corrosive sublimate will disinfect the souls. Goethe once said the most interesting book that could be written would be a treatise on the errors of mankind. Let us see to it that our mistakes may not swell that book.

OBSERVATIONS ON CHRONIC URETHRITIS IN THE MALE.[1]

By HOBART CHEESMAN, M.D.,

NEW YORK.

The following remarks are not intended by any means as an exhaustive treatment of the subject, but for the most part to present some personal experiences and observations.

Chronic inflammation of the urethra is essentially the same as that of chronic inflammations of other mucous membranes. Such points of difference as exist are mostly due to differences in anatomical and physiological conditions. The same kinds of lesion are found in chronic catarrhs wherever located, and, in general, the same principles are applicable in treatment. It is a disease liable to present serious difficulties to whatever special practice it belongs. The difficulties ought not, however, to be greater, as a general thing, in the urethra than in other organs. On the contrary, they might reasonably be expected to be less than in many, both on account of the greater accessibility of the urethra to local treatment, and also because nature has provided for the urethra, in the frequent voiding of urine, an efficient means of cleansing it from all morbid and irritating secretions. No artificial measures are likely to prove so effective for flushing out a foul urethra, thoroughly from end to end, as a forceful stream of urine from a full bladder. In addition to this, the urine can be made artificially medicinal or antiseptic by the administration of appropriate internal medication, such as balsams, salol, quinine, boracic acid, and other well-known therapeutic agents. Measures artificial, intended only to cleanse the urethra, would therefore seem superfluous, if not meddlesome. Passing from natural advantages, some of the artificial ones, recently acquired, are a knowledge of the normal size of the urethra and of how to detect stricture where formerly overlooked; knowledge of the importance of stricture as a cause of gleet; measures for radically removing stricture, as by the use of the dilating urethrotome and conical sound; the utilization of the endoscope in exploring for disease and for applying treatment; the proper use of ordinary urethral injections, of "deep" injections, and of medicated bougies. There are other particulars of the science and art of modern urethral surgery worthy of mention, doubtless, but these are the ones principally to be relied upon in connection with our subject. With such advantages, both natural and artificial, it would seem that this opprobrium of genito-urinary practice, which has so long stigmatized it, ought to be in a fair way of removal. This is not to be understood as belittling the difficulties, but only as expressing confidence in the potency of the means at command to overcome all ordinary difficulties. In other words, failure is no longer the fault of the profession, but, for the most part, of the individual practitioner.

The lesions found in chronic urethritis, like those in other chronic catarrhs, are of three varieties:

1. **Diffuse Inflammation.**—This may extend to the whole or any part of the urethra; may be superficial and appear like a torpid congestion, merely, of the mucous membrane, without evident erosions of the epithelium; or it may penetrate more deeply and give rise to induration and stiffening of the urethral sheath, to erosions of the epithelium, and to granulating surfaces.

2. **Circumscribed Erosions.**—The lesions may consist of circumscribed erosions or ulcers, more particularly behind, or in some connection with, stricture.

3. **Inflammation of Mucous Follicles.**—The common characteristic of all forms of chronic catarrh, and one of the most important in relation to practice, is the indolent nature of the inflammation, the lifeless and inert condition of the affected tissue. To arouse the affected tissue from this condition and restore it to healthful activity is to effect a cure, and therefore the main object of treatment. It is reasonable to suppose that essentially the same measures for this purpose are required in the urethra as elsewhere. In treating chronic pharyngitis we witness the prompt disappearance of granulations on the vigorous application of strong solutions of nitrate of silver. When studying otology, fifteen years ago, a patient who had had a purulent discharge for twenty years from the middle ear, in which granulations existed, was finally cured by instilling solutions of nitrate of silver into the tympanic cavity. Beginning with a very weak solution and gradually increasing the strength, when ten grains to the ounce had been reached the discharge suddenly ceased, and it has never returned to the present time. In this way indolent granulations were destroyed which had not been reached by applications made by other methods. I have observed in dispensary practice that the worst cases of balanitis and posthitis, where there is tight phimosis and the glans cannot be exposed (and the patient refuses circumcision), that by ballooning the prepuce for a few minutes with a solution of twenty or forty grains to the ounce of nitrate of silver, a cure will often be effected by one application. The distended prepuce should be squeezed and thoroughly fingered, so as to cause the injected fluid to penetrate all the diseased tissue. It causes no pain of consequence in chronic cases. Nothing, in my experience, will so quickly and so surely cure an obstinate eczema of the leg as the vigorous rubbing into the affected surface of a strong solution of silver nitrate. The essential thing for success in all these conditions has seemed to be that strong application be made and rubbed into, or caused in some way to penetrate thoroughly, all affected parts; and this will apply with equal force in stubborn cases of chronic urethritis. In cases of subacute or mildly chronic and uncomplicated urethritis, doubtless the judicious use of ordinary injections with a clap syringe, or other temperate measures, will generally prove sufficient. One of the most effective agents for the

[1] Read before the Manhattan Medical and Surgical Society of New York, January 24, 1894.

purpose of injection in these cases, according to my experience, is the permanganate of zinc, of which two grains to the ounce of water is ordinarily as strong as will be comfortably borne. The salts of zinc, I am convinced are the most efficient, on the whole, for urethral injections of anything yet approved by the profession; but evidently quite as much depends upon the method of using the injections as upon what is used. The urethra should be filled to distention in making the injection, after it has been flushed out with a bladder full of urine, reserved for the purpose; then the fluid should be retained in the urethra for two or three minutes by pinching together the lips of the meatus with one hand, while with the other the under surface of the penis is stroked and the urethra pinched and fingered all along its course, gently or more vigorously, according as the case is more acute or chronic, in order to cause the injection to penetrate thoroughly everywhere, even if possible into diseased follicles. Only one such injection should be used at a time, and, as a rule, repeated every eight hours; and its use should not be discontinued until a week after all signs of discharge have disappeared. The following case will serve as an illustration:

Case I.—The patient (sent me by a physician) was aged twenty four, bookkeeper, and had a gonorrhœa eight weeks old, which the attendant had been treating unsuccessfully for six weeks—in the ordinary way with injections and internal medication; and for two weeks, in addition to these measures, by passing sounds every two or three days. I discontinued the sounds, as the discharge was profuse and frankly purulent, and prescribed an ordinary zinc injection and a mixture of balsam of copaiba, giving the patient careful instructions how to apply the injection, as indicated above. On his return in three days, the discharge had already nearly dried up, and at the end of a week or ten days had entirely disappeared. Sounds were afterward passed every three or four days for a few weeks, to dilate what appeared to be several incipient strictures along the pendulous urethra. Many cases like this could be related, in which a chronic discharge has been observed to disappear promptly on simply instructing the patient in applying his injections.

When the discharge arises in the deep portion of the urethra, which cannot be readily reached by ordinary injections applied by the patient, deep injections should be made by the attendant of a mild solution of silver by preference in this class of cases every two or three days, or oftener, if practicable. In case the affection is not confined to the deep urethra, but exists also in the pendulous section, the installations made with the long catheter syringe may be distributed along the whole canal, drop by drop, as the nozzle is withdrawn. In this case the penis should be grasped behind the glans, and after the syringe is removed, the urethra fingered as described above. Quite strong solutions may be applied in this way in very chronic cases in which the whole canal is affected, without causing any pain of consequence or subsequent harm; but they need not be made so often in such cases as in more acute conditions. Mild solutions, however, should be first tried, and strong ones employed only as by gradual approach. The following case is an example:

Case II.—The patient was aged twenty-six, and had had one attack of clap several years previously, lasting five weeks. The second attack had occurred in October, 1891, and lasted until March, 1892. Ceasing then, it returned the following September, after coitus, for the first time subsequent to the last infection. The discharge at this time was only slight, until the attendant passed sounds down to the bladder, two weeks later, when it promptly became profuse and creamy. Notwithstanding this, the daily use of the sounds had been continued, the patient passing them himself by direction of the attendant, who, the patient informed me, was an expert otologist. This was continued until he called on me, November 24, 1892. The sounds were discontinued, and a zinc injection and an ordinary internal remedy prescribed. After a few days the discharge diminished to only a drop in the morning, of a sero-mucous character, and the patient ceased his visits, thinking, doubtless, to dispense with my further advice. But after repeated trials, finding the discharge reappeared every time two or three days after ceasing to apply the injection, he gave it up and again presented himself, about the middle of March, 1893. Instrumental examination disclosed several soft strictures, all within an inch and a half of the external meatus. These, except the deepest one, were reached and cut with a bistoury, and the latter was soon dilated by sounds, up to thirty-six, French, which sound could then be passed into the bladder comfortably, being the full size suitable to his urethra according to the rule of Otis. But curing the strictures did not cure the discharge as had been expected, although the use of the sounds was continued for several weeks after all trace of stricture ceased to be detected. Applications through the endoscope were next tried, varying in strength up to sixty grains of nitrate of silver to the ounce, wherever the affection appeared to exist, which was over pretty nearly the whole urethra. But they had no effect on the discharge. Resort was next had to the syringe for deep injections. The applications were made all along the canal, as described above, beginning in the prostatic region while the bladder contained urine, an important precaution, especially in using a strong injection, else coming undiluted in contact with the sphincter of the bladder, it is liable to prove uncomfortable. Only one or two grains of nitrate of silver to the ounce were applied the first time. The next time five grains to the ounce; the third ten grains, and so on, increasing by a few grains each time, until thirty grains were reached. Up to this time the discharge had continued about as usual, but after one application of the thirty-grain solution it ceased entirely and never returned, all treatment from that time being discontinued. None of these injections caused much smarting or discomfort at the time of the operation, but there would be more or less subsequently at micturition, lasting a few minutes, for the first twenty-four or thirty-six hours after the operation, and at this period an increase of thin secretion; but nothing more serious than this ever resulted from these applications. But several months later the patient called, complaining that he had been having pain for two or three weeks in the peroneal region, and upon my instilling four or five drops of a five-grain solution of silver in the deep urethra only, it caused severe burning for an hour or more and, for two days after, on micturition. Doubtless the greater tolerance on the former occasion was due to the toughening of the urethra and blunting of its sensibility by the protracted inflammation and by the almost equally protracted treatment. One or two grains to the ounce of silver, injected into a healthy urethra, is liable to cause exfoliation of the epithelium, as you who have tried it have probably observed.

Applications of silver, and other agents, through the endoscope will sometimes prove very effective in those cases, especially, in which the affection is confined to the surface and to that section of the urethra in front of the isthmus. Beyond this point it is not so easy to make applications effectively through the endoscope, and in follicular affection, in any part, they are useless. But it may be rubbed into any surface affections in front of the triangular ligament, sometimes very effectively, especially where granulations exist. Contrary to what, without experience, might be expected, quite strong applications may sometimes be rubbed thoroughly over large affected areas, at least as much as sixty grains to the ounce, without causing serious pain or other unpleasant consequences, and with very prompt benefit.

This is well illustrated in Case III. The patient was a single gentleman of thirty-odd years of age, whom I treated on two occasions only. The history was the ordinary one of several gonorrhœas, developing into incurable gleet. At least for two years it had proved incurable under experts of good reputation. Strictures had

been cut, sounds passed, the lacuna magna split up, deep injections made, and endoscopic applications, all in vain. The discharge continued sufficient to leave, every morning, a muco-purulent stain on a piece of white cloth on squeezing the penis; and there was also history of exacerbations, under the circumstances ordinarily exciting them in such cases. On the first occasion of my treating him, the routine measure being employed, that of the sound passing was applied. Three months later, sound-passing and endoscopic applications having in the meantime been practised, being again called to treat him, on introduction of the endoscope the urethra semed to be generally affected from the meatus back about two inches, beyond which it presented its normal healthy pink hue, and the sheath was perfectly soft and pliable; while in the affected region it was perceptibly stiffened and the surface was dark red and more or less covered with fine granulations. Upon the cork-screw extremity of a wire holder a cotton swab was securely twisted, and then dipped into a fifty-grain to the ounce solution of nitrate of silver. The swab was passed entirely through the distal end of the endoscope, introduced to the further limit of the affected region, and then rubbed back and forth behind the endoscope as the latter was withdrawn, over the whole affected region, very thoroughly. There was no complaint of pain at the operation. A prescription for an injection of permanganate of zinc, two grains to the ounce, was given for the patient to apply with an ordinary syringe, every twelve hours. He returned in two weeks, perfectly cured. He reported that the injection caused sharp smarting, for which reason, as directed, he had reduced its strength by adding an equal part of water, after having used it in full strength three or four times. The discharge ceased to appear after the fourth day from the operation, and the injection was discontinued, according to directions, four days subsequently. Several weeks later there had been no return of the discharge, and endoscopic examination showed a healthy-looking urethra. This cure proved as permanent as it had been prompt.

Case IV. is an example of a class in which, under unfavorable circumstances, all ordinary measures having failed, the patient is sent away with a simple prescription and gets well promptly. The patient first applied for treatment in June, 1890, with a history of several attacks of gonorrhœa. For some time the arrested discharge had had the bad habit of returning on slight provocation, such as indulgence in more wine than usual, tobacco, or venery. He continued to reappear every two or three months to be treated on such occasions. At first, ordinary injections and medication would dry up the secretion entirely in the course of ten days or two weeks, but gradually this ceased to be the case, and the morning drop at least became a permanent symptom as soon as the injections were discontinued. But he refused instrumental exploration, until becoming engaged to be married. He announced this engagement in April, 1892, and that he must be cured before October, and that he was ready to submit unresistingly to any measures advisable to this end. Exploration of the urethra disclosed only slight strictures, one just behind the meatus and two others, both in the first inch and a half of the urethra. These were divided with the expectation that the operation would cure the gleet. It did not, however. Neither did the subsequent diligent use of sounds, applications through the endoscope and with the deep urethral syringe. The whole urethra, as far as could be made out through the endoscope, was congested or inflamed. The patient was cashier of a large corporation, and at this season driven with work ten hours a day; and being a slight, nervous man, this, with hot weather and worry about his case, and with visiting his affianced four nights in the week, and spending the other evenings at his club—altogether, was exhausting. When he got to his club he would feel so depressed that, notwithstanding the best resolutions to obey orders, he would often yield to the temptation to brace up on alcoholic stimulants, and to quiet his ruffled nerves by too much smoking. But the greatest difficulty was to prevent his visiting his girl so often, and probably exciting himself sexually for several hours. I first sent him on a sea voyage, directing him to remain away a month; but in ten days he was home again. Notwithstanding the subtle opposition of the young lady, he was sent away again, promptly, to a farm-house on the coast of Maine, far from the madding crowd, taking a vial of permanganate of zinc injection and armed with a clap syringe. He came back in four weeks cured, and was married without unhappy consequences.

Case V. is an illustration of follicular inflammation. The patient was a married man, about thirty years of age. Had been treated in this country and previously in Europe for chronic urethritis and stricture. He had suffered for several years, at times seriously, having had several attacks of retention of urine. He was in a miserable state when I first saw him, the urine coming away after much straining, in driblets, accompanied with pain. Micturition was also very frequent, and there was a gleety discharge. Exploration showed the urethra strictured throughout nearly the whole of the first inch to a considerable degree, then it appeared free from stricture until a point three and a half or four inches from the meatus was reached. Through this point, after the anterior strictures had been cut with a bistoury, a seventeen (French) steel sound could with difficulty be urged; when, on manipulation over the sound, a firm nodule could be felt at the point, extending a third of an inch longitudinally. This was at first taken to be a callous stricture, and an operation with Otis's dilating urethrotome was advised. It being refused, sounds were passed every two or three days, and the nodule stretched and rubbed each time over the sound. It disappeared so rapidly that in three weeks it was hardly perceptible, and in six weeks the cure was complete. The conclusion was reached that the nodule probably had been an inflamed follicle with thickened walls, packed with inspissated secretion, which the pressure of the sound and massage gradually removed. Certainly it is not according to my experience that a tough annular stricture, such as this was at first supposed to have been, can be caused to disappear so readily by passing sounds. The cure has proved to be permanent.

No one of experience, probably, any longer advises to attempt the cure of chronic gleet, where stricture has been shown to be present, by other measures, until after the stricture is cured, either by urethrotomy or by gradual dilatation. But it is also probable that most of us are, by this time, pretty firmly convinced that curing existing stricture will not always cure the co existing gleet, although it is always a necessary preliminary in order to assure anything more than temporary suspension of the gleety discharge. The use of sounds in treatment of gleet, when stricture is absent, although a very popular practice, and sometimes effective in exciting health reaction and curing the disease, yet often proves disappointing in bad cases. It has seemed to me sometimes to be more productive of profit, in this connection, to the practitioner than to the patient. But for the radical removal of soft and yielding stricture, whether accompanied by gleet or not, it is indicated, while urethrotomy should be reserved for those cases which do not yield readily to dilatation.

It is most important to be able to diagnose incipient stricture, and to determine when a stricture has been radically removed. But we can determine these points only by reference to the normal calibre of the fully distended urethra. Therefore, to know what the latter truly is becomes most important. In this connection, Professor White, in Morrow's "Handbook" (page 18), remarks: "The figures which Dr. Otis gives, while they doubtless represent accurately the distensibility of the male urethra, do not by any means represent what can fairly be called its normal calibre. Dr. Otis's views and teachings have been of great value as showing the distensibility of the normal urethra—as bringing out the full pathological value of stricture, and adding exactness to urethral surgery."

This quotation would seem, on examination, to be only another way of stating very well, indeed, what Dr. Otis himself would express, and is misleading only in seeming, in connection with the figures and other statements of Professor White, to imply that his own teachings differ in some material respect from those of Dr. Otis. As a fact, the difference would seem to be only in that their respective figures refer to the urethra under different conditions. In other words, the only disagreement is as to what degree of distensibility the surgeon shall regard as the normal calibre of the urethra.

In the last edition of his book on stricture of the urethra, Sir Henry Thompson, who cannot be justly accused of lack of becoming conservatism, says: "Indeed the question of diameter of the urethra must be considered as resolving itself, to a certain extent, into the measure of its capacity of being safely extended, and this is of greater practical importance perhaps than any other question regarding it." Call it, therefore, distensibility or normal calibre. Practically these are the same; for it is evident that, whatever may be normal calibre, regarded functionally—regarded from the surgical point of view, it is when the urethra is fully distended, that is, to the limit sharply drawn by the inelastic fibrous sheath—where the elastic constituents of the urethra find their extension limited by the capacity fixed in the inelastic constituents of the sheath. Up to this limit the healthy mucous membrane easily expands, without danger of rupture, while the surrounding sheath of inelastic fibres, constituting this abrupt boundary, is too strong to be in danger of rupture by any ordinary force, such as is employed in exploring with the urethrometer or in passing sounds. But in case the mucous membrane has lost its elasticity by disease, it is readily seen how it might be liable to fracture, but not the sheath itself. The fracture of the mucous membrane alone would not seem, should it happen, a very serious matter.

Practically, the term moderately distended as applied to the urethra, has no determinable nor definable value, and is consequently meaningless to the surgeon.

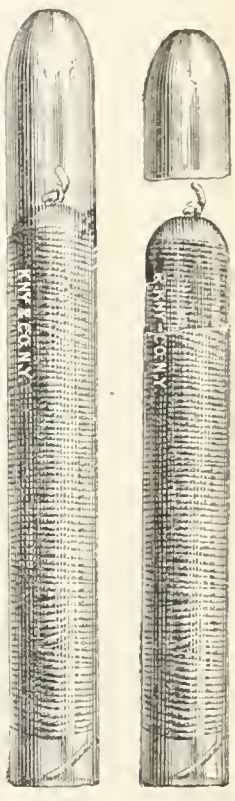
STERILIZED CATGUT IN A CONVENIENT AND PORTABLE FORM.[1]

By OTTO G. T. KILIANI, M.D.,

NEW YORK.

INSTRUCTOR IN CLINICAL SURGERY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; SURGEON TO THE GERMAN DISPENSARY.

Surgery in its present state of development is surely a great science and a great art. But the more elaborate our methods grow, and the better our technique becomes, the more does our success depend upon very small and apparently unimportant details. This is one of the reasons why I venture to bring to your notice to-night this little arrangement which is the subject of my paper.



One of the most important features of surgical technique is the material for sutures and ligatures, and its preparation. In all the cases where we wish to use absorbable material—and it is used now in our aseptic period, where most of the operations are expected to heal under one dressing, a great deal more than ever before—catgut is *the* material; and it would be used still more, if a good many surgeons had not lost faith in the possibility of sterilizing it. How important this question is, is shown by the fact that, for instance, I personally know of eighteen different methods of preparing catgut. There are very likely a great many more, in fact nearly every surgeon has his own method, or at least the "modified" method of somebody else. Now, it is a well-known fact that wherever a great many methods exist for achieving the same thing, and wherever new methods are constantly being invented, none of the old ones is satisfactory, and I should like, therefore, to hear your opinion about my method.

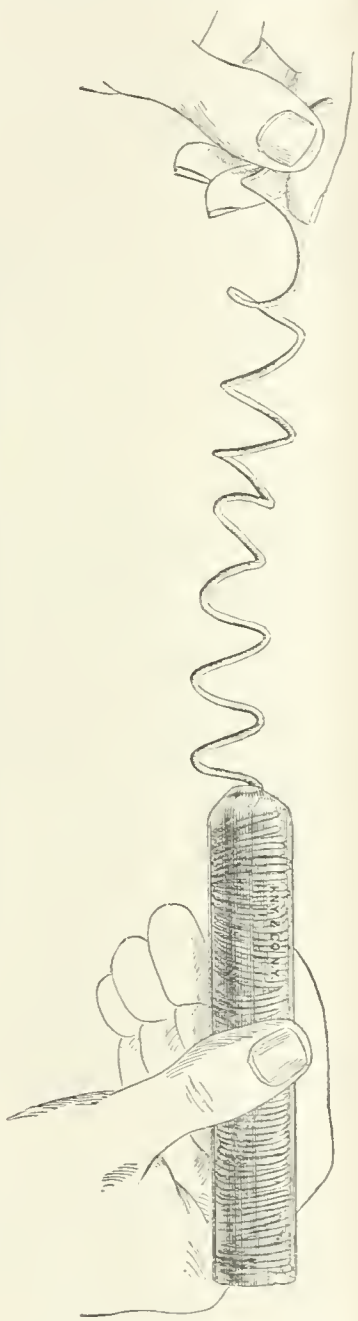
[1] Read before the Medical Society of the County of New York, April 24, 1893.

In preparing catgut for surgical use three points come into consideration, namely: 1. How to sterilize catgut. 2. How to keep the sterilized catgut in this condition. 3. How to make it portable in that sterilized condition.

Without entering into particulars concerning other methods, I will briefly describe my own, and we will then see how it answers these three requirements.

Dry catgut, not kept in oil, is put in absolute alcohol for twenty-four hours to remove all moisture. Then it is cut in pieces of two and three yards length, one of which is rolled on a glass rod, and then put in a glass tube open at one end, and with a little hole at the other, through which a short end of catgut is pulled. The glass rod is removed and the roll of catgut is in the glass tube. This tube with its contents is put in a second glass tube, a little wider and longer, with one end open. Then the filled tube is put in a dry hot-air sterilizing apparatus, the temperature of which is brought within one hour up to 80 centigrade, 176° F. This is to let the alcohol evaporate, and what might be left of water. Then the open end is closed by melting the glass, and the hermetically sealed tube is again put into the sterilizing oven, the temperature of which is brought up in the course of two hours more to 140 centigrade, 284° F., which is kept up for a whole hour. Another hour is consumed in letting the temperature gradually sink again. Then the outer tube is scratched with a file and it is ready for use. Immediately before using it, the outer tube is broken, as described below,[1] at the marked place, and the inner tube with its contents put for two minutes into the solution in which the instruments are lying, whether it be carbolic acid solution or soda solution, or whatever else is used. Then you pull out through the little hole as much as you need, and so gradually use it up; or if all is not used, the rest is thrown away. This is a most essential point, that each tube contains only just about as much catgut as will be needed for an operation; for an extended operation several tubes may be opened in succession; and that then it cannot happen, as it does in other methods, that the remainder of the unused catgut becomes infected. This, of course, only holds good when the unused pieces are thrown away.

Our bacteriological experience has shown any number of times, and shows every day, that all micro-organisms and their spores are definitely destroyed by the temperature to which the catgut is subjected. It was really entirely unnecessary to prove it again, and I have done so only for the sake of completeness. I have here tubes with pieces of sterilized catgut in the gelatine or agar, where absolutely no cultures are to be seen. Some of them contain catgut as it is in the market and then sterilized, some, catgut which I infected with pus or with cultures of staphylococcus pyogenes aureus and citreus, streptococcus, and anthrax, and then sterilized.



I have been making these experiments for over six months, and I never got a culture except sometimes by carelessness a non-pathogenic culture of asparagillus, the bacillus of mould.

But there is another question to be answered, and this

[1] The outer tube is broken as follows: A small piece of wire comes with each lot of tubes, it is heated red-hot in the flame of a spirit or other lamp, and on being placed upon the file-mark, cracks the glass cleanly. Or the tube can be easily broken between the fingers without danger of lesion, by wrapping some sterilized gauze around it.

is: Does sterilizing in dry heat not injure the catgut and impair its durability, elasticity, etc.? I am fortunately able to give a definite answer to this question.

Reverdin and Benkisser first employed this way of sterilizing catgut, and found out how not to injure the quality in the process. I do not know how much it came into general use, but Schede, surgeon to the new Hamburg State Hospital, had the catgut prepared in that way since 1889, and it was there, during my service in 1890, that I learned how to do it. Since that time I have had the method in constant use for my own work, and I never had reason to complain about it. So the experience of one of the largest hospitals in the world—Schede has six hundred surgical beds—speaks for it, besides my own experience. Now to the second point. How to keep sterilized catgut sterile. All sorts of ways have been tried to achieve this end, and everyone knows the different glass jars and bottles in which the catgut is kept, on glass spools in alcohol, with or without salicylic acid, chromic acid, carbolic acid, iodoform, bichloride, etc.

In my method of preparation it is beyond any doubt that the catgut, if it ever becomes sterile, must remain so forever in the glass tube which has been closed by melting And it seems to me to be a very important feature that the catgut is contained in a hermetically closed tube during sterilization, and therefore is absolutely safe from infection of any kind by handling, during or after the process.

The last point to be investigated is the convenience in carrying around. A great number of receptacles have been constructed and recommended, a part of which I have tried myself and found them all unsatisfactory. The reason is plain, as first, in all of them the catgut must be kept in a fluid, and secondly, these must all be refilled. I think this is the strongest point in favor of my preparation. Nothing can be easier and more convenient and handier than these little tubes. There is nothing to run out or spill, with reasonable care there is nothing to break, there is nothing to get out of order, and they are always ready for use.

It only remains for me to mention that the preparation will be very cheap, a point which will have some bearing on its use for general practice. It is intended specially for the general practitioner, and not only for the surgeon, whose operations are for the greater part performed in the hospital, where he can keep his catgut the way he prefers, or can have it sterilized according to his own liking.

For this purpose the firm of Richard Kny & Co., who are prepared to furnish this catgut, will also sell it unsterilized with the outer tube open, according to a suggestion made by Dr. Gerster when I spoke with him about it. It can then be easily closed by a wad of cotton instead of by melting the glass.

I know of only one objection which can be urged against the use of this preparation, viz.: That it is impossible to see whether the catgut is really sterilized. In this respect we have to trust to the makers, except that, as a further precaution, some specimens of each lot of sterilized catgut should be subjected to bacteriological tests before being put on sale.

It gives me great pleasure in conclusion to give credit to Dr. Francis Foerster, whose suggestion was the incentive in my attempt to perfect a portable form of dry-sterilized catgut, which I hope may prove of some practical value to the profession.

133 East Fifty-seventh Street.

PYOTHORAX AND ITS TREATMENT.[1]

By CARL BECK, M.D.,

NEW YORK.

Among all so-called surgical diseases none shows a greater prevalence in this city than empyema. Its predisposing cause is probably due to the rapid variations of climate, which favors so much the development of pleuro-pneumonia. If it be true that figures demonstrate its prevalence, it becomes evident by the fact that, during a period of eleven years, I have performed resection of a rib in this city in one hundred and forty-one cases for empyema. You will find a great difference in the statistics of European surgeons. So, for instance, with the one exception of Kœnig (seventy six cases during twelve years), some of the most eminent surgeons furnish reports of between ten and thirty-five cases treated likewise during the same length of time.

The *Universal Medical Journal*, of Philadelphia, in its last issue, June, 1893, published the statistics of empyema treated by F. C. Holt, of Christiania, from 1874 to 1891. It impresses the reader that the twenty-three cases operated upon during this time were regarded to be a large number.

The *St. Louis Clinique*[2] does not disdain to draw classical rules from the observation even of two cases. That under the auspices of antiseptic principles the question is still pending whether aspiration, incision, or resection should be the treatment is a deplorable fact, the explanation of which, in my opinion, can only be found in the fact that the general practitioner is seduced to attempt the solution of surgical problems, which lead to the fields of speculation. One of the few glorious exceptions is represented by Gerhardt (as shown in his excellent essay about diseases of the pleura).

When, last year, I was visiting one of the greatest surgical clinics in Europe,[3] on inquiry I was told by the chief that only one case of empyema had been treated in the surgical ward during the whole year, as the other cases had to be under the attendance of the physician on internal medicine.

At the last Medical Congress in Vienna no less than six methods for treating pyothorax were still advocated; they were:

1. The expectant treatment.
2. Simple aspiration (done once or more), recommended by Silly, Ewart, Kapteyn, Peri, Hughes.

[1] Read before the County Medical Society of New York, February 26, 1894. (Part read before the Pan-American Congress, Washington, D. C., September 8, 1893.)

[2] Arnot Spence, February, 1893.

[3] University Place, with five hundred thousand inhabitants.

3. Aspiratory puncture followed by antiseptic irrigation, recommended by Senator, Reichelt, Baelz, Kashimura.

4. Permanent aspiration (Bülau's method), recommended by Subbotin, Bowditch, Immermann, Leyden, Curshmann, and Playfair, and modified by Phelps.

5. Simple incision, recommended by Kussmaul, Bartels, Quincke, Ewald, Rose.

6. Resection of one or more ribs, recommended by Roser, Koenig, Schede, Bardeleben, Runeberg, Billroth, Rydygier, Weir, Bull, McBurney, Estländer, Ziemssen, Glaesser, Raczynski, Gerhardt.

There is no doubt that the latter method, resection, is gaining ground more and more, especially among and through the real professional surgeons, and it will be the endeavor of this paper, in analyzing the other methods, to convince you of their insufficiency.

It is particularly Koenig who deserves the most credit for having first offered clear, simple, and methodical indications of a true surgical character.

The genius of my great teacher, Gustav Simon, even at the pre-antiseptic era, found a way to heal old cavities by resecting from three to seven long pieces of ribs, thus enabling the thoracic wall to approach the retracted lungs.

I may be allowed on this occasion to give this eminent surgeon, who performed the first nephrectomy, due credit for this ingenious method, which generally is attributed to Estländer.

The last year saw us admire Schede, who obtained satisfactory results by removing even the whole thoracic wall. Ribs had been perforated already by Hippocrates, the great master, and by studying his book "De Morbis" one cannot help getting the impression that, long before him, opening of the chest-wall was a well-developed operation, the indication for which was well defined and must have also been based upon a very frequent and extensive employment of the different methods of incision by knife, cautery, or by perforation of a rib.

In the seventh book of the "History of Nature," Plinius, for instance, describes the case of a certain Pharæus, who, after having been given up by his physicians, wanted to die on the battle-field. But when thrust by a spear into the chest, pus escaped, and the seeker of death recovered—in fact being cured by the weapon in the hands of his enemy. Euryphon, of Knidos, is supposed to have saved the life of Kinesios by opening his thoracic cavity with the actual cautery.

There can be no doubt that, based upon nearly perfect diagnostic means, such operations were performed frequently and successfully during the great Hippocratic era, and that the most of its admirable knowledge had been lost during twenty three centuries.

Is it not astonishing that Hippocrates laid great stress upon frequently washing the patient with warm water, before the operation should be performed? Does this not appear like a dawning of aseptic principles, and explains so well why the successes of operations performed then were so excellent that some are inclined to doubt their truthfulness?

It would suit the spirit of our sterilizing age to be reminded of the custom of frequent washing by our Hebrew friends, which was made a religious rite by Moses, who must have been the greatest connoisseur of human nature. It is a pity that just this doctrine is so poorly appreciated by some of his Russian offspring.

A slight impression of what we must have lost of the immense knowledge of the school of Kos, and how highly educated Roman surgery must have been, one may gain by visiting the so-called house of the surgeon at Pompeii. The streams of water which were constantly flowing through the streets of Roman cities were certainly apt to remove germs. But more than that—and I do not know if it has ever been mentioned from this point of view—the exceedingly large number of small wells in the house points to the more or less conscious knowledge of the principles of asepsis.

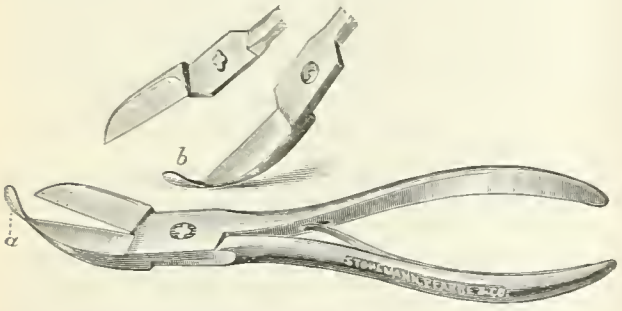
On a recent visit to this most interesting place I felt, more than ever before, how little advanced in fact we are in comparison with the medical civilization of many centuries ago. And why should not the ancient surgeon, with his fine art of diagnosis and with his powerful weapon—cleanliness—have obtained better results than the surgeon of not many years ago, who went directly from the autopsy room after having washed his hands, *secundum artem*, in a questionable fluid, to the operating-room, repeating his anatomical masterpiece on the living subject, and—with the same effect?

It is not at all astonishing that Sedillot, who brought the operation for pyothorax to light again, was not greeted enthusiastically. His results were so discouraging that the greatest surgeon of his time, Dupuytren, when suffering from pyothorax himself, being advised to be operated upon, declared that he would rather die from the hands of God than those of the doctors. Bearing in mind that Velpeau had lost all his cases, and that of fifty cases of empyema he had only seen four recoveries, we may well appreciate his conviction.

Later on Sedillot and Langenbeck recommended trepanation, Roser resection. But, as a rule, even among such surgeons as were in favor of resection, it seemed still to be understood that resection should especially be done in adults, while aspiration or incision should be preferred in children, because of their greater tendency to recovery. When I, nearly eight years ago, as far as my knowledge goes, for the first time[1] emphasized the adoption of the method of resection for all cases of empyema without regard to its original cause or to the age of the patients, in a paper before the German Medical Society of this city, my views were received very unfavorably. There was indeed not one gentleman present who had not obtained so and so many excellent results by aspiration or incision, that it was a crime to mutilate poor patients by resection without any necessity, and at the end of the discussion I had the feeling that the condemned Shylock was a nobleman in comparison with me.

It is a great satisfaction to me to know that several of the gentlemen present at that time are now of the same conviction as myself, and it seems to be difficult for them to remember that they ever were possessed of a different one. At the same meeting I, on the strength of twenty-four cases, maintained that the main indication for resecting a rib was not only, as usually supposed, furnished by the necessity of having sufficient drainage or to induce the thorax to approach the pulmonal pleura, but for enabling the surgeon to introduce his index finger, thus making it possible to palpate the pleural walls.

It is, as I repeat to-day, indeed the only procedure which with certainty shows the presence and allows the immediate removal of clots consisting of fibrinous or cheesy products attached to the pleura. My experience has shown me that in nine out of ten cases I could be certain to find such lumps—at an average of goose-egg size—free in the cavity as well as fastened to the pleuræ.



As long as we have no physical, mechanical, or speculative means to distinguish between this condition and a simple collection of pus, or so long as we cannot liquefy these lumps by the use of a dissolving injection first, aspiration and even incision are insufficient and therefore unsurgical procedures. I tried to dissolve such masses by the injection of pepsine, but without avail, as the resection later showed clearly. In three such cases large clots were found afterward. Anæsthesia was only administered when the pulse was strong. Generally caffeine was given before. In the greater number of cases the operation, which can be done in a few minutes, was performed under ether spray.

If the patient or his relatives are adverse to the seeming cruelty of this treatment, their attention can be called to the immense dangers to which anæsthesia might expose the organs of the thorax, the functions of which are so much impaired already by their compression. Not more than one or two drops of chloroform should be poured into the mask, the smell of which often gives the

[1] Cf. New Yorker Medicinische Presse, December, 1886.

patient the agreeable impression of getting or being insensible. This may explain why I never met with an accident during operation.

As the diaphragm after evacuation is always rising I usually resected the sixth rib. Only when the extent of the cavity is found to be very small, I incise above the same, using the aspiratory needle as a guide for the incision. As a rule, between the anterior and posterior axillary line—under antiseptic precautions, of course—I make an incision about three inches long, which at once divides the periosteum. From here the thoracic walls can be palpated equally well anteriorly and posteriorly. Furthermore, the patient, when brought on the edge of the table, can assume the dorsal decubitus, while, if the incision should be made further back, he would lie on the healthy side, which on account of the pressure of the effusion would expose him to great danger. Then with a small curved elevatorium I lift the periosteum from the rib, which then is pushed underneath the rib so that the rib rides on the instrument. A blunt hook retracts the tissues alongside the rib toward the axilla. One blade of a bone scissors is introduced below the rib between hook and elevatorium, and the same cut through. Then the elevatorium is pushed toward the sternum, thus forcing the rib from the last fragment of adhering periosteum, the hook inserted opposite to the wound, and with scissors the same manœuvre is repeated. If my own elevatorium shears (see cut) are used, it is only necessary to tear away the connection between the periosteum and the rib and cut the rib through, the instrument being of such a shape as to keep the tissue properly retracted. The one blade, if separated, can be used as an elevatorium, so that, without having anything else on hand than a knife and this scissors, the whole operation could be performed. A piece long enough to allow the introduction of the finger suffices.

It is impossible to strike the intercostal artery during these manipulations. Iodoform (as a powder or as a saturated solution in ether) is then distributed above the wound surface, to prevent infection from the pus as it flows from the cavity. Through a small opening made into the pleura with a bistoury a Pean forceps is introduced and the pus slowly evacuated. A sponge is pressed against the opening from time to time to interrupt the stream, to avoid a too rapid expansion of the lungs. (The time of evacuation should be at least twenty minutes.) The finger is now introduced, and lumps, which are now probably found to be adherent to the pleural walls, are wiped off with the index finger or with a blunt spoon made for this purpose (like a spoon for stone in the bladder). If bleeding should exceptionally occur, this may be deferred for two or three days. An irrigation of a bichloride solution (1 to 5,000) is used mainly for mechanical purposes, that is, to evacuate thoroughly. The pleura is then stitched to the skin with four iodoform silk sutures, forming a mouth (pleurostomia). These sutures at each edge of the wound and two opposite ones at its middle are generally sufficient to cover the wound surface, to prevent secondary hemorrhage, and keep the opening large. Some iodoform powder is put into the cavity to reduce the secretion, then the wound is covered with iodoform gauze. The whole side is protected by a piece of pasteboard-like absorbent moss, which, after being slightly dipped into a solution, adapts itself to the contour of the body like a plaster-of-Paris dressing. A strip of rubber adhesive plaster keeps it tight, so that no air can enter. During respiration it acts like an aspirating valve and absorbs at the same time. After three days a rubber drainage-tube, of the size of a man's index finger, secured by two large safety-pins in the shape of a cross, is introduced. I have refrained from introducing it immediately after operation, since I have witnessed considerable bleeding from it. Undoubtedly the constant respiratory movement of the pleuræ causes irritation in the way of rubbing. It seems that after the pleuræ become more accustomed to the contact of the atmosphere, as soon as granulations appear, they stand the irritation well. As the cavity is, indeed, entirely emptied after the operation, there is no necessity of washing it out afterward. As an average, two weeks after the operation a smaller drain is introduced, which gradually has to be shortened. When the serous discharge becomes scanty the drainage-tube may be left out and a small strip of iodoform gauze introduced. For the following few days the patient has to be watched very carefully. It may be that the cavity is obliterated the following day, but very often union is only superficial and retention of pus occurs, as an expression of which an elevation of temperature will be noticed.[1] Then, of course, the drainage-tube has to be introduced again, and after a week the same manœuvre must be repeated, until four days after the obliteration no secretion has been showing up and the temperature has remained normal. In doubtful cases the grooved director may reveal the presence of retained pus. The patient should always lie on the diseased side of his thorax, and should be lifted up by the feet about every four hours so that the pus will flow into the dressing. This renders the procedure, as advised by Küster, unnecessary, to make a counter-opening to avoid the retention of pus. There is no reason for introducing gauze into the cavity.

The dressing has to be changed twice a day for the first week, later on once a day, and after three weeks only every second, third, or fourth day. The patient, if in any way possible, should get up after one week. The thermometer is controlling the treatment, *i.e.*, the change of the dressing. During the after-treatment for the first few days small doses of morphine are administered for the purpose of immobilization. If the pulse be weak, strophantus or caffeine may be given at the same time. Later on, syrup. ferri iodat or cod-liver oil is ordered. Nourishment is given frequently in small quantities to avoid distention of the stomach. Great stress is always laid upon the necessity of gymnastics to prevent curvature. My experience leads me to the conclusion that simple empyema, operated early, will only under extraordinary circumstances turn out unfavorably. In other words, the chances of an empyema depend entirely upon the early diagnosis of the general practitioner. The diagnosis of empyema has to be made by the aspiratory needle. If there is much cheesy accumulation, or a small cavity, or if the fluid be encysted through the division of the cavity by adhesions, it has to be introduced quite often on different portions. I sometimes have explored ten times before I could corroborate my suspicion. I found it useful, when I could not draw any pus, to push the wire through the needle, a procedure which sometimes made a trifle of pus appear on the end of the needle.[2]

After deducting the 24 cases published seven years ago, 117 remain in this series. Among the cases 39 were below three years; 32 were between three and five years; 19 were between five and ten years; 10 were between ten and sixteen years; 17 above this age. Of them 12 died above sixteen years, 5 from tuberculosis; 98 were simple acute cases, 19 were complicated. Among 5 double-sided, 4 recovered.

In the case of a child, two years of age, where I had operated one year ago, and where recovery was perfect

[1] Cf. history of Case XIII.
[2] Cf. history Case IX.

four weeks later, I had to perform a resection after a second pleuro-pneumonia only four weeks ago on the same side.

All the empyemas with offensive odor (4 cases) died.

The average time of the healing process was five weeks. Recovery of a baby, aged six months, was perfect after six days.

Among the cases of simple empyema (collection of pus —*bonum ac laudabile*—following an acute inflammatory process in the lungs or pleura) in 63 the diagnosis was made early. These cases recovered without exception.

Among the 37 cases which were diagnosticated late, 5 showed the typical vaulting of the thorax. (In two of them a fistula remained; one of them died after resection of seven ribs.)

In 6 cases I was doubtful whether tuberculosis was causing the empyema, or if the long standing of the latter did not cause the tuberculosis. In fact I cannot understand how an accumulation of pus could occupy any portion of the body for months without causing sinister manifestations.

Two cases, where tuberculosis was diagnosticated, and therefore considered non operable, recovered after resection. So they, according to the wisdom of the dissuading capacities, had, as one would imagine, been treated wrongly.

Based upon this experience (similar cases of respective cures are reported by Schede and Güterbock),[1] I repeat that resection of a rib should be performed whenever the presence of pus has been verified by the exploratory needle, no matter if tuberculosis is confirmed or not. What harm can be done by resection? A consumptive has nothing to lose and everything to gain.

As before alluded to, the differentiation between tuberculosis and simple empyema is not so easy as it seems on superficial contemplation. An abnormal condition, for instance, at the apex does not necessarily show the tubercular character of the empyema, and *vice versa* bronchial breathing, râles, and bronchophony during auscultating, the symptoms of compression as well as forced pectoral fremitus, can all be due just as well to a tubercular infiltration of the lung tissues.

I may, for instance, relate the following history: A machinist, twenty-six years of age, showing an excellent family record, took sick suddenly, never having been ill before, with a chill and nausea. Pleuro-pneumonia developed, which ended by crisis. Perfect recovery, however, did not follow, but the patient went around for three months while suffering from slight dyspnœa and low fever. Four months after the onset of the pleuro-pneumonia I had a chance to perform resection, but three months later the patient died from tuberculosis. Now, was the acute inflammation already the expression of commencing tuberculosis? Hardly!

In the cases of so-called stinking empyemata other serious suppurative processes had been present. So it may be that the patient succumbed to the multiple pyæmic foci. So if I abstract the deaths caused by pyæmia and tuberculosis, only 5 cases, including the 3 Estländer operations, remain, where I can attribute the fatal result directly to the consequences of the operation.

My results of the so called Estländer's operation were little encouraging. Among 5 cases where I had to resort to it, I saw only 1 recover perfectly (3 died)[2] and another is still mourning his fistula.

In a case of thoracic fistula, existing for two years, I recently tried the following osteoplastic experiment: On a man, thirty-six years of age, who after an attack of pleuro pneumonia suffered from pyothorax, resection of a rib was performed only after repeated aspirations—that is, about six weeks after the onset of the suppurative process. The cavity did not fill up and a fistula still remained fifteen months after the resection. At this time the cavity would hold about a pint of irrigation fluid. The fistula was situated one inch behind the right anterior axillary line at the level of the seventh rib. Probe and finger introduced into the dilated fistula canal, proved that the cavity extended from the second to the eighth rib. Laterally in its centre it reached from the posterior axillary line forward to about an inch to the inner side of the sternum. According to my determination I made a semilunar incision from the upper margin of the second down to the upper margin of the eighth rib, dividing all the soft tissues at once. The beginning as well as the end of the incision was situated at the anterior axillary line. The middle of the segment nearly touched the sternum. While sharp hooks retracted the soft tissues, the periosteum was incised around each rib and with an elevatorium it was freed from its attachments. The rib was divided then with the bone shears. In this manner the third, fourth, fifth, sixth, and seventh ribs were cut through in the direction of the semilunar incision. Then they, still in their connection with the periosteum, could be pushed down into the cavity to a considerable extent. If I had had any difficulty in dislodging the ribs I would have resected pieces of them. The bleeding was insignificant. A very tight dressing consisting of sponges and boards of moss, pressed the fallen-in ceiling of the cavity inward, which had been previously scraped and was slightly packed with iodoform gauze (but only toward the dorsum). Every second day the dressing was changed and pressure made upon the flap. The patient's condition was not impaired by the procedure, and three weeks after the cavity would hold only three fourths of a pint.

Originally it had been my idea to make semilunar incisions, according to the periphery of the cavity, anteriorly as well as posteriorly at the same time, but the fear of insufficient nourishment of the flap prevented me from doing so. Therefore I preferred to divide the same ribs further back twenty-four days after the first operation, when the condition of the depressed portion was such that I could expect the circulation to be well restored. Now the sunken-in area forms a deep depression. In proportion to this two tablespoonfuls of the irrigation fluid is retained only by the cavity. The patient's general condition was very much improved.

It seems that I am justified in hoping for a permanent obliteration. Of course the adaptation of the thoracic wall to the pulmonal pleura is not as thorough at once as after total resection, but it is evident that, if my experiment proves to be a success, the patient enjoys the great advantage of not having suffered the loss of his bony support. At the same time I may call attention to the scant loss of blood, and especially to the impossibility of interfering with the intercostal arteries. (Further remarks about this case I reserve for a future communication.)

In reference to sero-fibrinous exudations I may state that I do not approve of resection as recently recommended in Germany. In this connection I may say that in two cases I have injected a ten-per-cent. mixture of iodoform glycerine, with success, into the pleural cavity, after having aspirated first.

In reference to the etiology, I found pleuro pneumonia occupying the front rank. Among the complete histories I found it eighty-four times, twenty-nine times after influenza; scarlet fever, eight times; puerperal processes and other septic infections, four times; whooping-cough, twice; and diphtheria, once.

As far as the pathological significance of empyema is concerned, I acknowledge that it is very different. The etiology as well as the extent of the exudation, the kind of pus (if thin, thick, smelling, or putrid), the age and constitution of the patient, the pulse, the temperature, the digestion, the subjective condition of the patient, and the stage of the disease, have all to be taken into consideration. Furthermore, it is of great importance to know to what particular microbe the empyema is due, that is if to the streptococcus, the pneumococcus, the tubercular bacillus, the typhoid bacillus, to the staphylococcus aureus or albus. Some empyemas contain simultaneously several forms of schizomycetes.

[1] Cf. Berliner klinische Wochenschrift of June 27, 1892, p. 655.
[2] Cf. histories

Netter, in 109 empyemas, found: streptococcus, 51 times; pneumococcus, 32; saprogenous organisms, 15; Koch's bacillus, 12 About half of all empyemas contain streptococci. As this microbe is most commonly found in suppurative processes, and has its domicile constantly in and on the most healthy persons, it is self evident that it frequently will be demonstrated in pyo thorax.

It seems that it especially tends to the formation of solid masses. Its predilection is for the infectious diseases of adults. The pneumococcus of A. Fränkel is more prevalent in the primary empyemas of children. About twenty-five per cent. in adults, and seventy per cent. in children.

This form of empyema shows the most benign character among all, so that some are inclined to attribute this to the microbe; but it seems to me that the vitality of the organs and the compliance of the thoracic walls, are the main causative factors of the more benign character of empyemas in children. The absence of the tubercular bacillus does not prove the absence of tuberculosis, as it very often is not found. There are empyemas where only Koch's bacillus is found, and there are some where streptococci, staphylococci, and several mixed forms could be discovered. In the latter case tuberculosis has repeatedly been diagnosed by other methods. There is still left a good deal for future investigations, to make these microscopical examinations more useful for the surgeon.

All these points certainly influence the prognosis as well as the after-treatment, but certainly could not prevent me from performing the resection, as long as there is the slightest hope for recovery. *As long as our diagnostic means are so insufficient, that we never are able to know, before the operation, exactly if the lung will expand in proper time or not, we from the start must make our arrangements in such a way that we can meet all eventualities afterward.*

It is certainly very disagreeable, if the patient, for instance, has been promised to be cured by incision, and then the ribs approach each other so much that drainage becomes imperfect and resection must still be done weeks after the incision! An occasion like this will hurt the reputation of the surgeon to the greatest extent.

Among the accidents I have witnessed, I may mention that, no less than four times, I have been called to extract drainage-tubes which were imperfectly secured (such as by one safety-pin), or where the rubber was of an inferior quality, so that breakage occurred. Once I removed a drainage-tube, nine inches in length, a year and a half after operation by Bülau's method.

Breakage of a poor rubber tube, however, occurred to myself once, but fortunately I was able to grasp it with the forceps the moment it slipped off.

Once I assisted a general practitioner (cf. history below) who, when trying to stitch the pleura to the skin, broke his needle. I fortunately was able to extract the fragment from the cavity, where, on a level with the second rib, it was already driven into the lung.

In analyzing the six different methods mentioned above, I can hardly say anything else about the value of the so-called expectant treatment, than that I regard it to be a crime. How men of the standing of a Leyden can maintain that empyemata, following pneumonia, are very quickly absorbed as a rule, I fail to understand. I hold exactly opposite views, that is, that absorption takes place only under the most exceptional circumstances, and if it really does, it seems to me to be a great misfortune for the patient, because this procedure most probably furnishes the first step in tubercular infection.

P. K. Pel [1] mentions that the principle, ubi pus, ibi evacua, has justifiable exceptions, and that if empyemata be of small size, if the general condition of the patient be excellent, the pulse slow and well filled, if no fever be present, and the appetite remain good, absorption through thickening can be expected. Now, if one should recover from such a healthy disease without having used the exploratory needle, diagnosis will certainly be doubted; and, on the other hand, if an aspiration should have yielded pus, who will dare to recommend expectant treatment? Simple aspiration is to be condemned because it may only cure some of such cases, where no clots are present, and, as we have explained above, we have no means of knowing of their presence otherwise than by making an opening which allows the introduction of the finger. So it is a hazardous procedure. When Pel says: "We, without performing resection several times, had perfect results," I may answer that I hardly know of any disease which, no matter how badly it was treated, has not occasionally been cured, in spite of bad treatment. It is a pity that the advocates of the aspiration never have an opportunity to see the clots, and therefore they are under the impression that there are no such things in existence. They are satisfied in aspirating a certain amount of liquid pus; the patient is relieved and gladly submits to a second and third aspiration, because a stab with the needle is indeed no operation, and the most unsurgical physician can perform it.

If the patient could with his intellectual eye see the lumps in his pleura, common sense would teach him, the layman, that they never can be aspirated. But as it is, he will be aspirated so long till he is emaciated; and he is sucked, in the truest sense of the word, till the lungs become contracted. Then, as a last resort, resection may be recommended, which at this late stage, when the expansion of the lungs is so much interfered with, usually proves to be a failure.

From this the aspirating enthusiast deducts that resection is an operation which yields a bad prognosis, and that "he never saw a good result from it." Albert says very well, in reference to aspiration: "This procedure is analogous to the pumping out of other abscesses, for instance, suppurating buboes. In such cases a variety of aspiratory instruments have been tried, and once in a while a cure was effected."

The only courageous and clear treatment is the broad opening.

This whole surgical business is strictly analogous to the interference of a badly trained midwife. It is a great satisfaction to me to state that among my personal professional friends, I have been able to convince every one of them of the incorrectness of aspiration, although they all, more or less, had experienced a few results with it. For conviction I needed only to invite them to a resection at the hospital, and when they had seen me remove the clots from the pleura, they confessed they did not have the slightest idea of their existence, otherwise "they would not have tried their adventurous policy."

Aspiration, however, is by no means an innocent manipulation. The irritation in the pleural cavity may produce epileptic spells, vertigo, nausea, fainting, and even fatal collapse. At the same time a nervous physician may interfere with an intercostal artery. (As reports show, death has occurred repeatedly through extensive bleeding)

Upon aspiration, followed by irrigation, only a few surgeons rely, so far as my knowledge goes. The idea to wash out solid particles is, of course, a very good one, but regarding the large size of the lumps, the evacuation through the small tube is absolutely impossible. Therefore, this method, which fifteen years ago was received with great enthusiasm, has dropped into deserved disuse, and in fact is identical with simple aspiration.

Nearly the same can be said about the aspiration followed by permanent drainage (Bülau's method). In cases of simple empyema of short standing, where the lungs still expand easily, or wherever there are no lumps present, this method would be the ideal one. It consists in puncturing the pleural cavity with a trocar, into which a rubber tube can be introduced, this being long enough to reach a bottle partially filled with an antiseptic solution.

Analogous to the syphon-drainage after lithotomy, the pus should be constantly aspired, as negative pressure in

[1] Zeitschrift für klinische Medicin, p. 211. Berlin, 1890.

the pleural sac is caused. But as the lump question cannot be settled before a free opening is made, this method is nothing but an interesting experiment, although the author's results deserve attention.

It is certainly very interesting, that once in a while fibrinous products, especially when tightly attached to the pleural walls, can slowly be absorbed. But as we, in fact, are not at all able to judge the conditions under which this takes place, and furthermore, as we, while trying to find out if the solid masses will be absorbed, or if we must not resect anyway, are losing so much precious time, it is only little better than the simple aspiration. Besides it is very probable that the absorption of the cheesy masses, if it exceptionally should occur, would favor tuberculosis. The tube, however, becomes easily displaced, so that its main advantage—the hermetical exclusion of the air—is void. Finally, the treatment can only be carried out in a hospital.

The method of simple incision has still many advocates, who claim that a small incision suffices. Furthermore, any general practitioner could perform the operation; while resection, a very difficult and mutilating operation, would require the skilful hand of an excellent surgeon. Resection should therefore be only performed in such cases where, after several months' treatment, the ribs have approached each other so much as to make drainage impossible.

In reference to the first point I may say, that if we open an abscess nowadays, we do not think that a small opening suffices, but we make the incision as broad as possible. Indeed, so wide that, if we have a chance, we try to overlook our whole field of operation. We may palpate the walls of the abscess and find, besides its thin lining membrane, necrotic tissues. After having noticed them, the immediate removal is a matter of course. Only after this do we mean to have evacuated our cavity thoroughly. Then we do not need to wash it out every day, as only a serous secretion is to be expected, and the natural sequence is a perfect and quick recovery.

Would a surgeon have the audacity to lance a large abscess anywhere else, to introduce a small drainage-tube, and to wash it out every day? Such surgeons perhaps change their antiseptic fluid once in a while, assuming this perhaps to be the cause of the insufficient progress? And where is the difference between this and a pleural abscess?

I am not able to overlook the field of operation and to introduce my finger into the pleura after incision. I can wash out small but no large clots, and it is impossible to diminish them inside. Furthermore, I cannot detect those clots which adhere to the pleural walls. So they undergo fermentation and if the patient's condition stands it, they become decomposed, and then, under repeated febrile elevations become dissolved and are then washed out. Therefore irrigations cannot be dispensed with, which are destroying those very adhesions which we need so much for the obliteration of the cavity. How important these adhesions for the agglutination are, has been emphasized already in 1865, by Dr. A. H. Smith, of this city.

That retention of pus is always present in this condition is self understood. In regard to the difficulty of the operation, I am confident that herniotomy or tracheotomy, operations which every general practitioner should be able to perform, are much more difficult. As far as the possibility of interfering with the intercostal artery is concerned, this accident, on account of the anatomical situation of the same, happens much more easily than during resection. The incision is only made as far as to the periosteum. Then with blunt instruments the tissues, in which the artery is imbedded, are pushed aside, so that it can easily be seen and avoided. For the same reasons there is no loss of blood, while after incision through the intercostal space, fatal bleeding has repeatedly occurred. In reference to the scarcity of the moving together of the ribs, I find that this condition is the rule. In fact it is a healing process, it is the healing tendency of nature itself which makes the ribs approach, and so the remedy itself in this case is a prevention of the cure, because it occludes the opening.

Altogether, the only rational method of treating empyema is the subperiosteal resection of a piece of rib. It is a clean, easy, safe, and nearly bloodless operation. It guarantees a large opening for a sufficient length of time, and the resected piece, if the periosteum has been preserved, is always restored. Scoliosis I have never observed, with the exception of one case of Estländer's operation.

Among the histories I may report the following:

Case I.—Mrs. B——, aged fifty-six, a widow, shows a healthy family record. In April, 1882, she had an attack of pleuro-pneumonia, which was followed by pyothorax. After several aspirations, each of which gave temporary relief, I was asked to make an incision. But I insisted upon performing resection, which was done in presence of Drs. Waechter, Stutzer, and George Stiebeling, of this city. During the three weeks following the operation hectic fever was almost continually present, which weakened the patient considerably. Irrigations were made daily. Nearly every third day, I confess to my own shame, I tried another irrigation fluid, in the erroneous supposition that "in hoc signo" I would be victorious. In this manner I used boric acid, salicylic acid, acetate of alumina, carbolic acid, chloride of zinc, and at last, in my despair even made irrigations with solutions of tinct. iodi and of argent. nitr., with a bad result, of course.

Just by accident I happened to introduce my finger to palpate the pleuræ. To my great surprise I found a large amount of adherent tissues, which I instinctively removed at once. On the following day the temperature was normal, and after a few weeks the healing process was perfect. So far as I know the patient is still enjoying good health.

This case taught me to carry out the principle of cleansing more extensively *a priori*.

Case II.[1]—A. L——, a girl aged one year, sickened with pleuro pneumonia on the right side. Pyothorax followed, which was recognized by Dr. A. Aronson, of this city.

Five weeks after the onset of the inflammatory process I performed resection. Six weeks later healing was perfect. Two weeks afterward pleuro-pneumonia developed at the opposite side. Resection of a rib was performed fifteen days after the beginning of the pleuro-pneumonia for an empyema of small extent. Lumps were present this time as well as at the first operation. Recovery took place three weeks after the operation, while being treated as an out-door patient.

Case III.—M. R——, a boy six years of age, took sick with acute inflammatory symptoms which were supposed to be dependent upon typhoid fever. Four weeks later Dr. L. Haupt demonstrated the presence of pus. Resection was done immediately. Lumps were present. Recovery was nearly perfect, when, four weeks thereafter, the parents suddenly left for California, where, as it seems, through great negligence, a fistula became established. After four years' stay the patient returned to New York, where I found him in a desperate condition. The old fistula led into a cavity which extended from the second to the fifth rib, and from the margin of the sternum to the right anterior axillary line. After having resected the second, third, and fourth ribs correspondingly, perfect recovery took place five weeks later.

Case IV.—E. F——, a girl fourteen years of age, suffered from pyothorax after she had gone through a pleuro-pneumonia, as stated by Dr. A. H. Stiebeling.

Four weeks after the onset of the acute symptoms resection of a rib was performed by me. (Lumps found.) After three months I was summoned again, as a discharging fistula still existed. I dilated and scraped. After an absence of five months I saw the patient again. Now I found that an assistant had performed resection of the sixth and seventh ribs, but only to the extent of a half

[1] Case presented to the German Medical Society, March, 1890.

inch, just to "make the rib sink in," as his idea was, but this scheme did not work, as the same *status quo ante* was still present. Now I resected a very long piece of the fifth, and two shorter ones of the sixth and seventh ribs corresponding with the roof of the cavity, which would hold about three tablespoonfuls of fluid. Four weeks thereafter recovery was perfect.

Case V.—Miss E. L——, thirty-three years of age, of good family history, took sick with chills and sharp pains in the right side. She had coughed a good deal, and about three weeks after the onset of the disease (undoubtedly a pneumonia) was able to be about again. After this she was treated by her physician for two months, but only occasionally, until chills and pain in the right side compelled her again to stay in bed.

Dr. L. Weyland, who was called in now, found a prominence of the size of a man's fist at the right thoracic wall, the centre of which corresponded with the sixth intercostal space. The diagnosis of an empyema necessitatis was made then and an operation performed by me without delay. Considerable improvement followed, but a fistula remained, which in spite of repeated scraping, gymnastic exercise, and pneumatic treatment in Williams's cabinet, could not be obliterated. Therefore I undertook a resection of the fifth and sixth ribs to the length of five inches, as corresponding with the middle of the roof of the cavity. This was followed by a considerable decrease of the secretion, but still a year thereafter the cavity had not filled up.

Two and a half years after the onset of the disease I performed a third resection (St. Mark's Hospital). After the patient had inhaled only a few drops of chloroform, pulse and respiration stopped. It was a long time before we succeeded in resuscitating the patient. I now, without administering any further anæsthetic, resected four ribs more (third, fourth, seventh, and eighth). The very large opening was covered with iodoform gauze. After the operation was over the patient, still lying on the operating table, overwhelmed me with the assurances of her gratitude, a fact that shows clearly that she did not consider the omission of further anæsthesia to be a cruelty. Six months later the cavity had become so small that it could hold only one-half tablespoonful of an irrigation fluid. In accordance with this the patient's general health was excellent. In spite of the removal of seven ribs altogether, only a very moderate lateral curvature could be noticed. During the epidemic of spring 1891 she became affected by the influenza, to which she succumbed quickly.

Case VI.[1]—A. N——, thirty years of age, from a healthy family, took sick with repeated chills, disturbances of digestion, and rapid emaciation. He was treated first for malaria at his home in South Carolina, but when a slight cough set in, he was supposed to be tuberculous, wherefore he was sent to New York, as at this time, under the jubilee hymns of the Kochian Tuberculine era, an antituberculous institution had been established. There, however, in spite of the hyperactivity of the hypodermic syringe, the art of diagnosing had not been forgotten, and it was recognized that an abscess, originally situated in the liver, had perforated into the pleural sac.

The patient was brought to my department in St. Mark's Hospital, where I, after having performed resection of a rib, could make out a cavity of the size of a goose egg in the parenchyma of the liver. The communication with the bronchi could be demonstrated by irrigating an antiseptic fluid. The first few times when I did this, the patient got such a severe attack of cough that he became dark blue in the face, and dyspnœa was so serious that I was very much alarmed. Finally, we both became accustomed to this phenomenon, and I could frequently demonstrate before my students the connection between cavity and lungs by irrigating. Six months after the operation the patient had gained thirty pounds, but there was still a cavity, wherefore I resected two ribs. Hereafter the cavity became smaller. I then lost sight of the patient. His general condition was excellent.

[1] Demonstrated before the German Medical Society of the City of New York, June meeting, 1892.

Case VII.—E. W——, boy, six years of age, shows a good family record. Three years ago I was called twice to perform intubation resp. tracheotomy for laryngitis. Each time I postponed the operation, and, as it is evident, with perfect success. (If intubation had been done, the result would certainly have been a good one, and it would naturally have been supposed that it had saved the patient's life.) Now, after a preceding pleuro-pneumonia, empyema had developed, which was aspirated, without success as usual. The house physician was desirous to perform a resection himself, and asked me to lend him a helping hand. Everything went on nicely until the operator, too ardent in his desire to get the needle through the pleura, drove the needle into the rib, so that the needle broke. The fragment could not be found. Although the optimistic colleague assured me that he saw it fall on the floor, I insisted upon palpating the pleural cavity. Here I soon discovered it at the level of the second rib, where it, being an inch long, had already perforated the lung. As the sixth rib had been resected, I could just reach it with the tip of my index-finger. By pressing it against the thoracic wall I at last succeeded in dislodging and making it fall down during inspiration. I had already given up hope of catching it this way, as I was afraid to push it farther inwardly by the use of a forceps during the respiratory movements, and had therefore thought of resecting the second rib. The patient recovered in spite of all, and as it is my principle never to allow a member of the family to be present during operation, this incident passed unnoticed.

Case VIII.—O. F——, boy of fifteen, took sick with pleuritis five weeks ago. The effusion first was of a serous and later on of a purulent character. When I was consulted by the house physician, I found the patient somnolent, in cold perspiration and with great dyspnœa. The temperature was subnormal and the pulse could hardly be felt. The exudation extended over the entire half of the thorax. I declared that, under these circumstances the operation should be performed without delay and without an anæsthetic. To this latter proposition the house physician objected most emphatically, especially because the father objected to the cruelty of such a procedure. When I declined to intermingle in this aspect of the question altogether, the colleague reproached me with injuring him in his position as the family physician.

I cannot spare myself the blame of having been thus intimidated and having sacrificed my scientific conviction to etiquette.

The punishment, however, was not long in forthcoming; after the patient had inhaled only a few drops of chloroform, the respirations, heretofore so frequent, stopped entirely and the face became cyanotic. I had insisted upon administering the anæsthetic myself, and was at once ready with tongue forceps, dilator, and electric apparatus. With this armamentarium and artificial respiration I, after half an hour's work, resuscitated the patient. Then the operation could be performed without any objection to the not administering of the anæsthetic, so that at last the patient did well.

This was a good lesson for the colleague as well as for myself.

Case IX.—S. R——, girl of ten, four weeks after the onset of pleuro-pneumonia was aspirated for empyema in a hospital of this city. One week later an incision was made. When six months hereafter recovery did not take place, a resection was performed. This was done with a chain-saw, and just as much of the rib had been removed as to enable a thin lead pencil to slip through the opening. Into this small canal a rubber drainage-tube of the thinnest calibre was confidentially introduced, which after it had courageously resisted the permanent rush of the retained pus, at last resigned and broke beneath the safety-pin, which alone kept it *in situ*. As the parents moved just at this time to Long Isl-

and, the dressing was not changed for nearly a whole week.

It was reserved to Dr. Voegtle there to ascertain the error loci of the drain-fragment. With his aid I performed a more thorough resection, and could then, as introduction of my index-finger was very easy, extract the fugitive tube without any trouble. Scraping of a large amount of granulations completed the procedure. Four weeks later recovery was perfect, after the poor child had been aspirated, incised, and resected, first with saw and then with shears.

Case X.—In reference to the case of the tubercular machinist mentioned above, I may state, that on account of insufficient technique the exploratory needle, although repeated by one of the most prominent authorities of this city, yielded no pus. On account of this, the well-developed dulness was supposed to be due to an infiltration. Three days later, when I saw the case for the first time, I aspirated three times until I found pus.

A more striking illustration of the difficulty of the exploratory technique is the following case, which shows how grave an error I committed only a few months ago:

Case XI.—A. R——, two years of age, of a good family record, was sent to my office with a letter from Dr. Moskiviecz, stating that the child had suffered from pleuro-pneumonia, and that this was followed by empyema. Aspiration had yielded pus, and so he had referred the patient to me for operation.

The parents took the child first to another physician, a very well-known diagnostician in this city, and one who has had much experience with empyema. After several aspirations, in which he failed to find pus, he stated that no operation was required. The child not improving, it was brought to me. I made six aspirations, and then the parents objected to its further use, so I became somewhat perplexed and did not give any positive opinion about the case, although the symptoms of dulness, weakened respiration, and the history were in favor of empyema. The question of operation was, therefore, deferred for twenty-four hours. The next day pus was found and the operation performed.

After resecting the rib I found a small cavity filled up with an immense cheesy mass, only about half a tablespoonful of pus being present in the cavity. The aspirating-needle undoubtedly had been inserted into the mass repeatedly, and could naturally draw no pus.

Case XII.—L. I——, aged twelve, had developed empyema after pleuritis. The exploratory needle yielded pus. On the following morning I had determined to operate on the child at St. Mark's Hospital; but during the night repeated attacks of cough, lasting several hours, brought on a considerable amount of expectoration.

On the morning I repeated the explorations a dozen times without finding pus, so that I, regarding this rapidly improved condition of the patient, restrained from operating. Shortly after perfect recovery took place. I assume that in the night, perhaps induced by the puncture, perforation into a bronchus had taken place.

Case XIII.—M. T——, a girl aged eight, with the same history, recovered after I had drawn pus. On the following day, before I wanted to operate, I could not find any more pus, even after I had aspirated a dozen times.

In this case no cough had been present. Perhaps there was a connection here between irritation by puncture and rapid absorption.

Case XIV.—M. L——, aged six, strong boy with good family record, took sick, after having swallowed a considerable amount of orange kernels. He located his very sharp pains in the right iliac fossa, had vomiting and slight convulsions. The temperature was 106° F.; pulse, 144; respirations, 42. It was not at all unnatural that the house physician thought of appendicitis, much more so as one of the patient's comrades had, during play, taken gymnastic exercise by jumping on his abdomen.

One of our most prominent surgeons was called in at once, who, as he could not ascertain any resistance in the right iliac fossa, advised expectant treatment. The right leg of the patient could be lifted without causing any pain. At the same time I had a chance to examine the patient. I got the impression that a difference of sounds was obtained by percussing the right lower lobe. But as the nuance was only slight, and people as a rule do not have much confidence in the percussion of a surgeon, we agreed to have a well-known specialist for lung diseases present, who indeed, when he had examined the child on the following day, could now easily make the diagnosis of pleuro-pneumonia.

Three weeks later I performed resection for empyema. The patient improved rapidly, until the house physician, three weeks later, tried to do without a drainage-tube. The opening obliterated outside at once, but a few days afterward chills set in. As no subjective symptoms, especially no pains, were present, typhoid fever was thought of by the attending physician, a diagnosis which was corroborated by one of the greatest clinical teachers of this country.

When I was called, two days later, I, by forcing a grooved director into the old scar, could easily demonstrate the presence of pus. It is superfluous to say, that its evacuation cured the "typhoid" immediately. A drain was introduced again, and eighteen days later perfect recovery had taken place.

LOCOMOTOR ATAXIA, WITH REPORT OF A CASE CURED.[1]

By T. E. SCHUMPERT, M.D.,

SHREVEPORT, LA.

SURGEON TO THE CHARITY HOSPITAL, AND MEMBER NATIONAL ASSOCIATION OF RAILROAD SURGEONS.

The pathological histology of posterior sclerosis of the spinal cord is well determined, although our knowledge of the true nature and development of the lesions and theory of the disease is somewhat speculative. The exact beginning of the sclerotic process has not yet been determined. Some pathologists maintain that the disease is parenchymatous, *i.e.*, that the original change is in the nerve-filaments, while there are as many, on the other hand, who hold that the disease is interstitial, and that the nerve-elements are wasted because of the pressure exerted upon them by the hyperplastic neuroglia. The walls of the blood-vessels are thickened at the expense of their calibre, their elasticity gone, thus causing a trophic degeneration because of the impeded circulation; they are bound by inflammatory adhesions, as are also the pia and dura mater, thus tracing the line of a chronic inflammatory process. Tabes dorsalis is very insidious; while the original site of the disease is in vastly the majority of cases in the spinal cord, and especially in the lumbar or dorso lumbar regions, it may begin in its upper extremity and linger there for years, with such obscure and questionable symptoms as double vision, pain in the head, vertigo, etc. There are also some well authenticated cases where the peripheral nerves seem to have suffered the primary lesion; and that the disease was not due to propagation by contiguity of the spinal lesion, was shown by the fact that the larger nerve-trunks were free. Since, therefore, there is good reason for believing that the original focus of disease is at times in the nerves, and that the spinal cord is subsequently affected, it would appear that both pathological changes are the result of a common cause; during the latter stages of the disease the sclerosis of the posterior column involves also the posterior portion of the lateral column, and the general muscular atrophy which supervenes is in proportion to that of the cord, and therefore an index to same.

[1] Read before the Shreveport Medical Society.

This now hereditary disease is a disease of middle life, its cause usually very obscure, although syphilis seems to strongly predispose to it; its progress is unaltered by specific treatment. So great is the relationship between locomotor ataxia and syphilis that it is claimed by authors of no less renown than Professor Strumpel, that it only occurs in syphilitics; this, however, is highly improbable. Immoderate exposure to wet and cold, especially when combined with exhaustive labor, seems to have had decided influence in the production of some cases; there are numerous causes assigned, but it is most likely that a number of causes enter into the make-up of the one disease.

Locomotor ataxia is generally considered an incurable disease, although it does not *per se* compromise life, as the sufferer whose misfortune it has been to contract this disease is often left as a burden for his family to bear for a quarter of a century; but usually life is sooner or later cut short by some intercurrent disease, such as disease of the kidney or heart, to which it has predisposed. So much for a brief reflection of the pathology, etiology, etc. Gentlemen, the case which I am now about to present in Mr. J. M—— interests one, first from a pathological standpoint, and secondly, because of the interest we always feel in our patients for the patients' sake. Mr. M—— has been with us now a little more than a year, is fifty-one years of age, an ordinary day laborer (a ditcher). Hereditary history good. About ten years ago was first told that he had heart disease, and which he has unmistakably to this day; about the same time dimness of vision and vertigo. Two years since, numbness and a tingling sensation began in the four extremities, simultaneously with muscular weakness, a girdle sensation about his lower abdomen. Was admitted in the hospital September 19, 1892, in a very anæmic condition, which has been growing worse ever since, until, as you will now observe, it is profound. The paræsthesia has extended to his thighs and shoulders. His gait is slow and faltering, with slight locomotor ataxia and a great sense of fatigue of the lower extremities. Eight months since his feet and legs began to swell; at times his fæces are voided involuntarily, but as yet has complete control of his bladder. Pupils of his eyes are dilated, knee-jerk obtuse. There is marked both sensory and motor impairment, with sharp, darting pains. This condition, both of pernicious anæmia and of his heart, I believe to be the result of degeneration of the spinal cord, the heart trouble I believe to be only a symptom. It would seem that his cervical, lumbar, and sacral regions are at fault, and that the dorsal had been spared. In 1879 Vulpian called attention to the frequency of valvular disease of the heart in locomotor ataxia, and his observations are fully corroborated in this case. I believe the lesion to be strictly trophic and due directly to a centric nervous disease, the heart muscles themselves as well as the valves being involved, and which is but in keeping with the patient's general condition.

He has taken iodide potash, bichloride mercury, digitalis in its various forms, strophanthus, nitro-glycerine, various chalybeate waters, and preparations of iron of highest repute. In spite of all this his anæmia grows more profound, all remedies directed toward his heart seem utterly powerless to meet their indication, for this organ is unimpressed by any drug or size of its dose, maintaining throughout its irregular pulsations at first regular, next intermittent, then dicrotic. His nervous symptoms are steadily though surely stealing their way to the vital parts. Now I propose to place him on heroic doses of strychnine. I will begin with one twentieth of a grain and increase it to intolerance As it is a known fact that this drug has the power to restore nerve energy, to build up exhausted nerve-tissue, to revive the nerve-cells, and to enrich the blood by increasing its red corpuscles, it also has a tonic effect on the heart; by increasing blood-pressure it slows its beat.

Six months later I have prosecuted my plan, and here is the result. His anæmia is all gone, instead of the blank exsanguinated sallow face that was presented before, there are now to be seen numerous blood vessels coursing through his skin, his complexion a beautiful pink; is stout, robust, and active; his gait steady; his step nimble, and I defy anyone to detect a heart-murmur. In fact every symptom of disease has left him. Picked up, as it were, in that "pray that I might die state," and landed in his present condition of perfect health. He had often prayed that he might die. I began his treatment: ℞. Strychniæ sulph., gr. ij.; aquæ, syr. simp., āā ℥ ij. M. Sig. Teaspoonful every four hours, thus giving six doses in twenty-four hours. My next ℞.: Strych. sulph, gr. ijss., aquæ, syr. simp., āā ℥ ij. M. Sig.: Teaspoonful every four hours; and so on, thus adding a half-grain to his four-ounce mixture as oft as it was taken, until he arrived at ℞.: Strych. sulph., gr. vijss.; aquæ, syr. simp., āā ℥ ij. M. Sig.: Teaspoonful every four hours. When he began to evince slight toxic effect of the drug, thereafter his dose was increased more slowly, only a quarter of a grain being added each time instead of a half, and a few days' intermission at different intervals. He has just finished a bottle containing one-third of a grain at a dose, or two grains for the patient a day; but I will not push it farther, as I deem it unsafe; the patient had unmistakable clonic spasms of the leg flexors and back. At one-sixteenth of a grain the physiological effects of the drug were observed but never after that until about three-sixteenths of a grain was taken, a tolerance at that point seemingly having been established. This unprecedented strychnia dosing not only demonstrates the large amount that some patients may take when kept under careful observation, but it also shows that strychnia is not cumulative, as is claimed by materia medica.

The success of every physician depends on the number of sure remedies for certain diseases that he is familiar with. Now, if strychnia can be laid down in this limited category of sure cures as a specific for locomotor ataxia, a long link will have been snatched from the chain of incurable diseases, and another stride of advancement made in the circuit of a physician's sole professional aim in life.

CHANGE FROM MYOPIC ASTIGMATISM TO HYPERMETROPIA.

By F. T. BOWLES, M.D.,

NEW YORK.

THE change from myopic astigmatism to hypermetropia is so rare that I am led to report the following case:

June 16, 1892, Mrs. M. S ——, aged thirty, was examined by me at the Manhattan Eye and Ear Hospital, with the following result, viz.:

Javal, Rt. Eye, 3.0 D. ax. 105° V. 15°.
" Left " 3.0 D. ax. 90° V. 180°.
O. D. $\frac{20}{50}$ + : $\frac{20}{40}$ W. −2.5 D. cy. ax. 15°.
O. S. $\frac{20}{50}$ − : $\frac{20}{30}$ W. −2.5 D cy. ax. 180°.
Javal No. 1, 8 inches to 15 inches, with above glasses.

These glasses were ordered after three examinations.

They were worn constantly for several months with absolute relief from asthenopia, and with improved vision.

During the past few months they were discarded, as she was conscious of a gradual improvement in her sight.

On January 14, 1894, the following record was made:

Javal, Rt. Eye. No Astigmatism.
" Left Eye. No Astigmatism.
O. D. $\frac{20}{40}$: No glass.
O. S. $\frac{20}{30}$: $\frac{20}{20}$ W. + .50 D.

The glasses ordered in 1892 now give vision $\frac{20}{100}$ as opposed to $\frac{20}{30}$ then.

154 WEST NINETY-THIRD STREET.

Street Nomenclature and Medical Celebrities.—The naming of streets has been created in Paris into a fine art, and the memories of eminent citizens are kept green by this means. The name of the late distinguished histologist, Charles Robin, will henceforth be thus associated with a portion of the Rue Claude-Vellefaux, which has been rechristened Rue Charles-Robin.

Progress of Medical Science.

Treatment of Renal Insufficiency. — According to Rochester we should not try to stimulate into activity an organ that is inflamed or degenerated by the use of drugs that excite functional activity of such organ. In the case of the kidney, we should rarely, if ever, have recourse to stimulating diuretics, or to diuretics which, like digitalis, act by increasing the arterial pressure, until we have relieved the venous congestion by diaphoresis or catharsis, or both. Attention to diet is of the utmost importance in these cases. In order that the materials to be excreted by the kidney may come to that organ in the most unirritating form, the metabolic process should be carried to completion; this is to be accomplished by regular systematic exercise, which is to be obtained by massage when active exercise is not advisable, by inhalations of pure oxygen gas when it is evident that sufficient oxygen is not obtained from the air, and by the dilution of the katabolic materials by drinking large amounts of distilled water, or one of the mildly alkaline waters, such as Bethesda, Poland, or Buffalo lithia water. The anæmia that accompanies these cases should be met by the use of oxygen and iron. As the symptoms indicative of this condition are the result of toxæmia which depends upon the non-elimination from the body of certain katabolic materials that should normally be carried off through the kidneys, and as these organs are in such condition that they cannot do their work, all other avenues of elimination should be opened up for the escape of these poisons. This is to be brought about by exciting the activity of the skin by means of hot air or steam baths, accompanied and followed by vigorous massage, keeping the bowels open by means of salines and by washing away the contents of the colon, thus keeping the mucous membrane in a proper condition for excretion, with copious enemata of slightly alkaline water, occasionally followed by a high enema of 500 or 600 cubic centimetres of pure olive oil, as suggested by Fleiner—*New York Medical Journal.*

Nitrogenous Diet and Hot Water in the Treatment of Obesity.—In *The Lancet*, says the *Therapeutic Gazette*, January, 1894, Savill gives an account of his treatment of obesity that presents some features of special interest. A man, five feet ten inches in height and weighing two hundred and eighty-four pounds, was admitted to the Paddington Infirmary to be treated for an ulcer on the leg. This patient, sixty-eight years of age, was unable to walk, chiefly by reason of his bulk and partly on account of stiffness of the hip joints due to morbus coxæ senilis. There was a history of gout and a suspicion of chronic Bright's disease. Earlier he had been put upon the same plan of treatment about to be described, for obesity and ulcer of the leg. The ulcer had healed and weight had been reduced from two hundred and ninety four pounds to one hundred. But in a month or two both conditions returned. Upon the second admission he was put upon a diet of one pound of cooked fish and one pound of lean cooked meat a day, and a pint of hot water sipped at intervals every two hours. The fish and the meat were distributed in meals, according to the taste of the patient, but no bread, vegetables, milk, or any other article of food was allowed. The patient was a person of intelligence and did everything toward the success of his treatment, managing to drink five or six pints of hot water during the day. Weight decreased steadily. On admission, September 21st, it was two hundred and eighty four pounds; on October 2d it was two hundred and seventy-four pounds; on November 18th it was two hundred and fifty-six pounds, and on December 4th two hundred and forty-six and a half pounds. At Christmas there was some latitude given in diet, and the result was a prompt addition to his weight of seven pounds; but by January 15th weight was reduced to two hundred and thirty-nine pounds. After four months treatment, the diet was modified by the addition of two small slices of bread and butter at breakfast and supper, and milk and sugar in his tea night and morning. On February 7th, he returned to ordinary meat diet, such as other patients had, with the exception of potatoes. He then weighed two hundred and thirty four pounds and a half. Weight increased slightly for a time after resuming ordinary diet; but on March 21st, when the patient left, he weighed two hundred and thirty and a half pounds, having lost over fifty pounds in six months. The ulcer healed within four weeks of his admission, and pain and stiffness soon disappeared, permitting as much walking as the space in the ward would allow. Weight remains the same (two hundred and thirty and a half pounds), the man being now on ordinary diet, but drinking no beer. His health is excellent. The treatment is something like that adopted by Marienbad. The rationale is apparently that the patient lives upon his own fat, supplying from his own economy the necessary hydrocarbons and carbohydrates which are absent from the diet.

Simultaneous Intra-uterine and Extra-uterine Fœtation.—Dr. Vargas has described a case of twins which gave rise to very contradictory diagnoses, and ended fatally. The patient was a young woman employed in a cigar factory, who had had three children. She complained of pain, weight, and discomfort in the right iliac region, and was supposed by the medical men who saw her to be suffering from salpingitis or an incipient uterine tumor. After a time, however, it was considered that she was pregnant, and she was delivered of a seven months child which lived a month. The pain in the right iliac region continued, and when Dr. Vargas saw her he found that, though the neck of the uterus had closed, there were unmistakable signs of a second living fœtus, and he hoped that it might be retained till its full time. The patient soon afterward sent for another medical attendant, who, detecting no signs of life, diagnosed a uterine fibroma, and proposed an operation, to which the woman would not consent. Her condition, however, becoming worse, she sent again for Dr. Vargas, who found her dying of peritonitis. At the necropsy a putrid fœtus of about seven months was found in the peritoneal cavity, the uterus being quite normal. There must, therefore, have been a fœtus both in the uterus and outside it, the former being born at about seven months, and the latter dying shortly afterward.—*The Lancet.*

Treatment of Soft Chancres by Heat.—According to Dr. Lorand, this mode of treatment is based on the observations of W. Boek and of Aubert, the latter of whom found that chancrous pus heated to 40° C. became non-inoculable. The method is as follows: Water is conducted by two pipes, one carrying hot and the other cold water, to a copper reservoir, and is there kept at a temperature of 50° C. by means of a gas-jet. From the reservoir the water is carried by a rubber pipe to a coil of lead tubing, through which it circulates, and then escapes by another rubber pipe. If the water in the reservoir is kept at 50° C. it is found that when it reaches the coil it has a temperature of about 41° C., below which it must not be allowed to fall. The ulcers are dressed with pledgets of cotton-wool soaked in warm water, any undermined edges being first snipped off. A layer of moist wool is then applied round the penis, and over this the lead-tubing through which the hot water is kept flowing. Another layer of wet wool covers the tubing, and the whole is covered with gutta-percha tissue. The dressing is changed three times a day. Lorand saw about twenty cases, in some of which the chancres were both numerous and large, treated in this way. In the majority it was found that after two days' treatment the ulcers were clean and healthy, and then the secretion was no longer inoculable. The patients were then allowed to go home, and were treated as out-patients. The sores usually healed quickly under the application of dermatol.—*Wiener medizinische Wochenschrift.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, May 19, 1894.

THE LUNACY COMMISSION ADMIRES ITSELF.

IN the New York *Times* of May 13th the State Lunacy Commission receives a four-column exploitation of its "splendid work accomplished in five years." One-half of the article is devoted to eulogistic biographies and pictures of the modest members of the Commission, who have, as they admit, "paternal supervision" over the management of the insane asylums. We are told that the "able and disinterested men who make up the Commission" have "placed it on a plane that is the recognized model to-day for all the other States in the Union." Whether the plane or the Commission is the model is not quite clear from the context; but the general idea is most amusing to those who know the history of the Commission. The story of the Commission's work is simply a special plea and an apology, with those facts only given which would redound to the Commission's credit. Its mistakes, its arrogance, its stupid interference with the pettiest details of the asylum management, are of course not referred to, nor are any facts presented in their justification.

We are told that the Commission has won its victory in the last Legislature over the superintendents. It is true the bill to abolish the Commission did not pass, but the Commission has received a lesson which it already is taking to heart. Asylum managers and superintendents are now being treated with considerable courtesy; and the Commission is evidently carrying in mind both the experiences of the past winter and the possibilities of next November.

THE REVISION OF THE CODE OF ETHICS.

THE Committee on the Revision of the Code of Ethics of the American Medical Association has prepared a majority report, which shows how difficult it is to formulate definitely and satisfactorily rules of conduct for one hundred thousand men, pursuing, indeed, the same avocation, but living under vastly different social and economic conditions.

The Committee have taken the old Code as a basis, and have touched it up here and there to meet the demands of certain sections of the country. The Revision will no doubt be perfectly satisfactory to many, while others will say, and indeed already have said, that the Code is not revised but destroyed.

The three principal points of contention are those of advertising, of taking out patents, and of consulting with homœopaths. Regarding the first matter, the Section is amended so that it reads:

"It shall not be considered as a violation of the spirit of this section, however, for physicians engaged in the work of medical education, either singly or associated in colleges, *or for physicians practising in hospitals, whether private or public, general or special,* to announce the fact or allow it to be announced to the profession *in the advertising pages* of strictly medical journals, or for physicians devoting special attention to one of the recognized special departments of medical practice, to note the fact on *their signs or private cards.*"

Now, in many parts of the country, East, South, and West, it is considered in very bad taste for a physician to announce his specialty on his sign or his card. It is only quacks and irregulars who do it. Some will contend that it is in reality only a matter of taste whether such things be done or not; others that the custom is a good one, while many more condemn it as the entering wedge to a prospective system of promiscuous advertising. We belong to the last class, and we have tried, on many previous occasions, to show why, from the point of view of morals as well as business, the practice is unwise. We are very glad to know that it is a custom not gaining any foothold except in a comparatively small area of the country.

As to the question of taking out patents, the amended Code will read as follows, the italicized words being those which have been struck out by the committee:

"It is 'derogatory to professional character . . . for a physician to hold a patent for *any surgical instrument or medicine, or to dispense* a secret nostrum, *whether it be the composition of himself or of others.* . . . It is also reprehensible for physicians to give certificates attesting the efficacy of *patent or* secret medicines, *or in any way to promote the use of them.*'"

This practically permits the physician to take out a patent, and allows him, if he wishes, to attest the efficacy of patent medicines, which, be it remembered, are not secret, since their composition is known at the Patent Office.

The propriety of a physician or surgeon taking out a patent is still a much mooted question. It does not seem to us to be a very important one, for, practically, there are very few patents which bring much money to the inventor. And if physicians were allowed to take out patents there would probably be no difference in prices to the profession or the public. Still we appreciate the fact that many feel keenly that the practice would lessen the reputation of the profession for humanity and unselfishness.

As to the question of consultations, the Code, as revised, says:

"No intelligent practitioner who has a license to practise from some medical board of known and acknowledged legal authority, and who is in good moral and professional standing in the place in which he resides, should be refused consultation when it is requested by the patient."

This strikes us as most sensible and wise. We do not see how any objection can possibly be raised to it. If the committee would leave the other items unchanged and insert only the above paragraph, it would do a high service to American medicine.

former having greater strength and more persistent action. The gum over the inflamed root being dried, a piece of the leaf of suitable size is cut, and this is simply pressed into place, where, as a rule, it will remain as long as a capsicum plaster. Leaves may be kept moist in a tin box with a tight-fitting lid, in the interior of which is a damp sponge. In pyorrhœa alveolaris a common symptom is an intense itching, almost akin to pain and perhaps more intolerable, provoking a constant desire to rub the gums. This pruritus, probably the result of the chronic gingivitis, is homologous to eczema, and readily disappears with the employment of one of the essential oils, notably that of peppermint, used as a mouth-wash or tooth-brush tincture. Where pulps are acutely inflamed Mr. Nichol advocates the heroic treatment of drilling into them with the dental engine, and maintains that the relief obtained more than compensates for the pain of the operation. Perhaps it does; but it must surely be rare to find a patient willing a second time to submit to a similar proceeding without an anæsthetic.—*Lancet.*

The Lancet on an Income Tax.—Sir William Harcourt has, says *The Lancet*, like all his predecessors, failed to give that consideration to the professional classes in the matter of income tax for which they are always looking, and always looking in vain. He has failed to recognize the great difference, for taxing purposes, between the incomes of men which are earned by hard and exhausting labor, dependent on the continuance of their health while engaged in the pursuit of an arduous and risky profession, and the incomes of men derived from investments which do not cease even with life itself. It is, we think, surprising that Sir William Harcourt, the scope of whose sympathies we consider broad, did not venture to recognize a distinction so obvious and so just.

The Healthiest City in the World.—According to the *Glasgow Evening News* it appears that the latest statistics issued by the German Imperial Health Department give to Berlin the honor of being the healthiest city in the world. The death-rate is given as only 16.3 per 1,000. The unhealthiest city, states our contemporary, is Alexandria, which, despite its unvarying fine weather, its three hundred fountains, and its soft sea-breezes, has a death-rate of no less than 52.9 per 1,000. Immense London occupies a favorable position with a rate of 20.3; but Stockholm and Christiania are better off with rates of 16.9 and 19 respectively.

American Medical Association.—The coming meeting of the American Medical Association at San Francisco promises to be a most enjoyable and profitable one. The Committee of Arrangements has spared no effort to provide also for the social entertainment of the members, and the many points of interest in and near San Francisco are of a nature to satisfy the most sanguine expectations. Provisions have been made for a stop at Yellowstone Park, so that those wishing to spend some time in this paradise of nature may do so without any increase in railroad fare.

The New York State Board of Health.—It is announced that the secretary, Dr. Balch, has resigned, and that Dr. J. S. Barnes, of Watkins, has been elected to succeed him.

Epileptic Colonies.—At the last business meeting of the Allegheny County Medical Society a series of resolutions was passed strongly commending the so called colony system as the best-known plan of caring for the indigent epileptics of this State. Drs. C. C. Heisman, T. M. T. McKennan, and T. D. Diller were appointed a committee to urge the State Society at its coming meeting in Philadelphia to adopt the same resolutions, and take measures to bring the matter before the Legislature.

Infection and the Communion Cup.—A correspondent writes: "Your timely warning on 'Infection and the Communion Cup,' in your issue of May 5th, is of interest to both clergy and laity. There seems to be no reason (after the consecration of both elements) why the bread or wafer should not be moistened with the wine, dried, and reserved for future administration; or I would suggest for those who desired to communicate in two forms, that a small quantity of wine be inclosed in soft gelatine capsules fashioned in the form of grapes, or in gelatinized tablets of unleavened bread, which could be handed the communicant from the chalice at the proper time. The latter would be in better taste than 'the small individual tumblers' used at Rochester."

The Picture of Paré for the Academy.—The painter of the picture of Paré presented to the Academy of Medicine, was Martout, not "Marbout," as printed in the notice of the meeting. The card announcing the meeting was primarily faulty in this respect.

The Library of the Academy of Medicine will be closed during the summer months to give the contractors opportunity to put in the new stack-room. The growth of the library since the erection of the new building has been phenomenal.

The Bureau of Nurses of the Academy, recently organized, has already been placed upon a successful working basis. Through it a reliable nurse can be engaged at the small expense of two dollars to the family of the sick, a sum which the bureau has found it necessary to charge in order to defray its expenses.

Medicine and the Constitutional Convention.—Several of the medical societies have appointed committees to advise with the Constitutional Convention, at Albany, with regard to matters of interest to the public health, the medical profession, and medicine in general. This is further evidence that the profession is awakening to the importance of its position in the community.

A Medical Mayor.—Dr. Charles A. Wheaton, of St. Paul, has accepted the nomination for Mayor of the city on the Republican ticket.

Journalistic Enterprise. — Under this heading the *Journal of the American Medical Association* says: "We congratulate our esteemed contemporary, the New York MEDICAL RECORD, on its cable reports of the Eleventh International Medical Congress. The first instance of the kind, we believe, attempted in American medical journalism." While thanking our esteemed contemporary for these kind words of appreciation, we beg leave to say that this is not the first instance of the kind, for a reference to the files of the MEDICAL RECORD will show that cabled reports of the Copenhagen meeting in 1884, and of that in Berlin in 1890, were also presented to our readers.

Sand.—The latest popular therapeutic craze is the use of sand—common, every-day sand—for dyspepsia. It is simply swallowed, but might be much more effectual, if applied with the stomach-cleaning brush recently devised by an ingenious Chicago man for scrubbing the inside of this much-abused viscus.

The Omaha Medical College held its commencement April 2d, and graduated a class of seventeen.

Naval Surgeons Wanted.—A telegram from Washington says that no one seems anxious to enter the Naval Medical Corps. There are eight vacancies, and some difficulty is encountered in finding young physicians able to stand the severe examination of candidates. The Board of Examiners is in session at Brooklyn, and is anxious to have medical students and young physicians appear as candidates.

The Craig Colony for Epileptics.—The Board of Governors has elected Dr. Frederic Peterson, *President*, and G. S. Ewart, *Treasurer*. The Legislature appropriated $140,000, but only $12,000 will be available until July, 1895. The colony can hardly be organized, therefore, until another year. The appointment of Dr. Peterson as President is a just recognition of his persevering and faithful efforts in behalf of the scheme.

The Philadelphia County Medical Society and the American Medical Association.—At a meeting of the Philadelphia County Medical Society, held on April 18th, the following resolutions were adopted:

Whereas, The Code of Ethics of the American Medical Association declares it derogatory to professional character for a physician to dispense or in any way promote the use of a secret nostrum, and the American Medical Association, by a resolution unanimously adopted at its meeting in 1892, forbade the advertising of such nostrums in its *Journal*; and

Whereas, The *Journal* of the Association has continued to advertise such nostrums, and in defence of its course in this particular has published an anonymous personal attack on a member of the American Medical Association and of this Society;

Resolved, That the Philadelphia County Medical Society respectfully demands that the trustees of the *Journal* shall, in their public official acts, respect the spirit and letter of its Code of Ethics, and that the columns of its *Journal* shall not be used for the anonymous personal abuse of its members in good standing.

Resolved, That a copy of these resolutions be transmitted to the Medical Society of the State of Pennsylvania, to the American Medical Association, and to the weekly medical journals.

(Signed) T. B. Schneideman, *Secretary*.

The Brooklyn Naval Hospital.—It is announced, but not authoritatively, that this hospital is soon to be greatly enlarged and modernized, and it is said to be the Surgeon-General's conviction that he will be able to make it one of the finest naval hospitals in the world.

Lactophenin, a New Analgesic and Hypnotic.—M. Landowski has given a successful trial to this new product in the wards of Professor Proust. This substance differs from phenacetin in that lactic acid takes the place of acetic acid. It is a white powder, tasteless, and soluble in 330 parts of water. The ordinary dose is sixty centigrammes (nine grains), repeated thrice in the twenty-four hours; but each dose may be increased to (a maximum of) fifteen grains. In small doses it has shown itself effectual in calming the pain of neuralgia; in large doses it is hypnotic. It is perfectly tolerated by patients who cannot take antipyrin. In some instances it provokes diaphoresis.—*The Lancet.*

The National Association of Railway Surgeons.—The seventh annual meeting was held in Harmony Hall, Galveston, Tex., on May 8th, 9th, 10th, and 11th, under the presidency of Dr. W. J. Galbraith.

Death of Dr. Cusco.—The death is announced of Dr. Cusco, of Paris. His name, although perhaps unfamiliar to many, will long survive in connection with the bivalve vaginal speculum in common use in France, and invented by him.

A Scotchman's Modest Sanitary Expectations.—Dr. R. W. D. M. Cameron, of Lanarkshire, Scotland, expresses the following insular sentiments in *The Sanitary Journal*: "What, under favorable, but perfectly attainable, conditions, ought the general death rate to be? Dr. Richardson's ideal rate of 5 per 1,000 is one of the blessings that will perhaps come to us with the millennium. In our present imperfect state, according to Dr. Farr, we may certainly aim at a general death rate of 17 per 1,000 living, and consider all deaths above this number as being due to artificial, and, therefore, preventable causes. In many country districts, where agriculture, the healthiest of all occupations, is the prevailing industry of the people, the mortality is often as low as 15 or 16 per 1,000, and it is certainly no Utopian dream to fancy that a good time will come in the no-distant future when 14 deaths per 1,000 living will be taken as the standard for rural districts, and, say, 17 per 1,000 for towns."

Dr. Cameron could certainly never have heard of the St. Paul Minneapolis sanitary Utopia with its 9 per 1,000 death-rate.

The American Academy of Medicine, which is to meet at Jefferson, N. H., August 29th and 30th, proposes as the subject for its papers and discussions the dependent, defective, and delinquent classes. A perusal of the outlined programme forcibly recalls to mind the burden that society carries. Besides the delinquents, there are classified: The sick poor, or dependents; the blind, deaf-mute, insane, the epileptic, feeble-minded, the inebriate, the permanently disabled, all of whom are defectives. Besides these three groups, society will in time deal more effectively with a fourth, viz., the infected. The American Academy of Medicine has chosen a very large subject, and one of which comparatively few physicians are competent to speak authoritatively.

A Society that takes no Recess.—The Académie de Médecine at a recent meeting discussed the question of summer holidays. During the autumn the sittings continue, but evidently very few members are present. Nevertheless, the majority of the members decided that matters should remain as they are; and rejected the proposition that a permanent committee should be appointed to give advice on urgent cases occurring during the vacation.

Society Reports.

ELEVENTH INTERNATIONAL MEDICAL CONGRESS.

Held in Rome, Italy, March 29, 30, and 31, and April 1, 2, 3, 4, and 5, 1894.

SECTION IN SURGERY.

(Concluded from p. 571.)

Arthrectomy.—Dr. A. Merea, of Cagliari, said that up to the present time the best result of resection of the joints had been anchylosis, due to the fact of the joint being immobilized after the operation. In four cases recently operated upon in Professor Biondi's clinic in Cagliari no retentive bandage had been applied, and the result was that there was free movement in every normal direction. From a study of these cases, and from the results of experiments on animals, the author had arrived at the following conclusions: 1. In the after-treatment of arthrectomy it is advisable not to apply any immobilizing apparatus. 2. Active and passive movements ought to be made as soon as possible after the operation—even as early as the second day. 3. Immobilization of resected joints favors the transformation of the synovial membrane into granular tissue, and the denuded articular surfaces then become the seat of osteophytic new-growths favoring bony anchylosis.

Suture of the Heart.—Dr. Del Vecchio, of Naples, had made a number of experiments on animals to determine the feasibility of suture of the heart, and had come to the conclusion that such an operation was practicable notwithstanding the continuous and active movements of the organ. He presented to the section a living dog operated upon February 20th. He had made two wounds in the heart, one incised and the other lacerated, closing the first with a single silk suture and the second with two sutures, one silk and the other catgut. The wounds made were in the right ventricle. The operation on the dog was more difficult than it would be on man, since the anterior mediastinum is wanting in the former, and hence the operation is complicated by the necessity of opening one of the pleural cavities.

Ovarian Cyst.—Dr. Sacchi, of Genoa, reported a case of cystic tumor of the ovary occupying the retroepiploic cavity, and pushing forward the pancreas and gastrocolic omentum. The cyst, when small, had passed through the foramen of Winslow and had then developed in the cavity where found. The tumor was removed by operation, but the woman died a few months later from cancer of the liver.

Dermoid Cysts of the Ovary.—Dr. Pascale, of Naples, reported two cases of this nature operated upon in the surgical clinic of Naples, and presented a number of conclusions arrived at from the clinical and anatomical study of them.

Abdominal Surgery.—Dr. E. Micheli, of Bologna, reported four cases among those operated upon by him in the Portomaggiore Hospital during the past two years. The first was one of echinococcus cyst of the pelvis. Laparotomy was performed, and the entire cyst was extirpated. The patient made a perfect recovery. The second case was one of enormous cyst of the ovary. The weight of the sac alone, the walls of which were half an inch in thickness, was nearly three pounds. The cyst was adherent to the abdominal wall anteriorly, and to the intestines. Ovariotomy was performed, and the patient made a good recovery. The third case was one of rupture of the uterus during parturition, four pints of blood being poured into the peritoneal cavity. Laparotomy was performed eighteen hours after the accident. The woman died on the third day from exhaustion. The last case was one of interstitial fibroma of the uterus. Abdominal hysterectomy after Zweifel's method was performed. The patient had several convulsive attacks soon after the operation, but ultimately recovered.

An Ovariotomy Trocar.—Dr. Micheli also presented a trocar for use in ovariotomy. The instrument was a modification of one already in use for several years. It made traction on the sac, thus doing away with the forceps of Museaux, and effected evacuation of the cyst without the danger of leakage of the fluid into the peritoneal cavity.

Rupture of the Ligamentum Patellæ.—Dr. Ferraresi described an operation for the relief of this condition. He resected a strip four inches long, one inch broad, and one fifth of an inch thick, from the median tendon of the quadriceps muscle, leaving it attached by its upper extremity. He then divided and stripped back the periosteum of the patella, and cut out a groove in the bone to accommodate the tendon, attaching the lower end of this to the ruptured ligament and then suturing the periosteum over it. In case the ligament was torn from the tuberosity of the tibia, he sutured the dissected tendon directly to the tibial periosteum. The same procedure could be employed in the treatment of fracture of the patella, only in this case the fibres of the tendon ought to be spread out so as to cover the anterior surface of the patella, and be attached to the insertion of the ligament into the lower fragment of the fractured bone. A similar method might be used in cases of fracture of the olecranon process, the tendon of the triceps being dissected in the same way.

Radical Cure of Hernia.—Dr. Poullet, of Lyons, described a method devised by himself, which was applicable to either inguinal or femoral hernia. He removed a strip of periosteum from the pubic bone, leaving it attached on one side only. This strip was turned upward in case of inguinal hernia, and laterally and downward in femoral hernia, and sutured to the aponeurosis of the inguinal or femoral ring.

Castration in Painful Oöphoro salpingitis.—Dr. P. Postempski, of Rome, read a paper with this title in which he advocated the small abdominal incision recommended by Lawson Tait. He had performed the operation in seventy-seven cases with very good results, the pain having disappeared in almost every instance immediately after the operation.

Sarcoma of the Kidney.—Dr. T. Ferretti, of Rome, reported a case of this nature in which the growth of the tumor was exceedingly rapid. The morbid process began in the endothelial cells of Bowman's capsule and soon produced atrophy and destruction of the Malpighian bodies. The glomeruli increased in size, and when they had attained about four times their normal volume a mucous degeneration took place in their centre, having the appearance at times of a myxoma. Many of the glomeruli gradually became confluent. The straight and convoluted tubes resisted the longest the invasion of the round cells of the sarcoma. The simultaneous development of the tumor in a very large number of glomeruli would point to a common cause invading different points. A careful examination failed to reveal the presence of coccidia, which are, in the author's opinion, in any case only degenerative bodies, and in no sense the cause of the sarcomatous process.

Splenectomy.—Dr. Tricomi, of Padua, reported eight cases, with seven recoveries and one death. The fatal case was one operated upon for the relief of splenic leucæmia. The spleen weighed 2,530 grammes. The patient died from shock four hours after the operation. The other cases were operated upon for wandering spleen, 2, simple hyperplasia, 2, and malarial hyperplasia, 3. In the cases of simple hypertrophy the spleens weighed 1,080 and 1,300 grammes, and in the malarial cases, 968, 975, and 725 grammes, respectively. The first operation was performed in December, 1891, and the last in January, 1894. The patients had been recently examined and all were in good health, and most of them were seemingly well nourished. In two cases the removal of the spleen was accomplished by medial laparotomy, and in the others by a curvilinear incision extending from the lower border of the left rib to the anterior superior spine of the ilium on the same side.

Ligature of the Splenic Artery.—The author also reported a case of this nature which he had performed on a woman, aged thirty-three, suffering from leucocythæmia. The immediate effects of the operation seemed favorable, the temperature never rising above 100.5° F. The secretion from the wound was, however, very profuse, pieces of the spleen coming away constantly with the discharge, and the patient finally died, forty-five days after the operation. At the autopsy the spleen was found to be friable and disorganized, only the portion around the hilum having a normal appearance. The ligature was firm. The author had found but two other cases of ligature of the splenic artery reported, one by Küster, and one by Vyman. In both cases the patients had died shortly after the operation.

Surgery of the Stomach.—Dr. Carle, of Turin, reported fourteen cases of operation upon the stomach for non malignant affections. Eleven of these were pyloroplastic operations, one gastro-enterostomy for stenosis complicated with hemorrhage, one divulsion, and one resection of the pylorus. There was one death, the results in the other cases being excellent. The following were the conclusions arrived at by the author from his study of these cases: 1. In chronic gastric catarrh, rebellious to medical treatment, it is permissible to resort to an exploratory laparotomy. 2. When a condition is found to exist rendering evacuation of the stomach difficult or impossible, it is necessary to perform some operation to remedy the defect. 3. It is absolutely essential to provide for free evacuation of the stomach, for it is better that the organ should be incontinent than that stagnation of the gastric contents should exist. 4. The successful result in the case of gastro-enterostomy, proved to the speaker's satisfaction, that ulcer with hemorrhage can be treated in this way more satisfactorily than by resection.

Chondroma of the Bones.—Dr. N. Rossi, of Rome, reported three cases of osteoid chondroma with myxomatous and sarcomatous degeneration, two of them in rachitic persons, and formulated a number of conclusions concerning the origin of the growths and the causes leading to the sarcomatous and myxomatous degeneration.

Operative Treatment of Knock-knee.—Dr. G. Melloni, of Rome, read a paper on this subject. Section of the internal condyle of the femur for the correction of genu valgum was first performed by Ogston, of Aberdeen, in 1876, and was generally adopted by English and German surgeons. It afterward fell into disuse, being replaced by Macewen's method of linear osteotomy. While admitting certain advantages of the latter method, the author declared his preference for Ogston's operation, as modified by Reeves, in cases in which there was very marked increase in size of the internal condyle with but moderate curvature of the femur. The dangers of the operation may be averted by scrupulous attention to antiseptic details, and by making a very neat section of the condyle while sparing the articular cartilage. The deformity resulting from vicious union of the fragments, or from incomplete ossification, sometimes seen after Macewen's operation, is rendered impossible by the procedure advocated by the author. He presented a boy, aged sixteen, upon whom he had performed this operation for double knock-knee with perfect results.

Ether versus Chloroform.—Dr. E. Micheli, of Bologna, had made a careful study of ether narcosis in Bruns's clinic at Tübingen, and had been led to accept the views of those clinicians and physiologists who give the preference to this form of anæsthesia. He grouped the objections to the use of ether under four heads: 1. Imaginary inconveniences (intolerance of ether in infancy and old age). 2. Inconveniences which were once real, but which have now been done away with by improvements in the technique of administration; such were incomplete muscular relaxation and a prolonged stage of excitement. 3. Inconveniences possessed by ether in common with chloroform (temporary albuminuria, nephritis, vomiting). 4. Inconveniences proper to ether alone, occasionally present contra-indications to its employment; those contra-indications exist in lesions of the respiratory tract, compression of the trachea, by goître, for example, and when it is necessary to employ the actual cautery in operations upon the face or neck. The author would by no means banish chloroform altogether, but would employ both ether and chloroform according to the indications present in each individual case, giving the preference, where there was room for choice, to ether.

The Peritoneum as a Suture Material.—Dr. L. Avangino, of Cagliari, said that a perfectly satisfactory material for sutures and ligatures had not yet been found, neither catgut nor silk meeting the requirements of the surgeon in all respects. A good suture should be made of animal tissue, easily disinfected and readily absorbed. The fibres of the parietal peritoneum of the ox answered these requirements in a most satisfactory manner. The author obtained the membrane from a freshly killed ox, and after stretching it upon a plate of glass, removed the layer immediately beneath the endothelium, cutting it into strips of varying length and width; these strips are at once twisted into fine cords and dried for twenty-four hours. They are soaked for five days in a five per cent. solution of sublimate in ether, and then in a two per cent. solution of sublimate in alcohol of 97° for ten days. The material is now ready for use and is preserved in a mixture of four parts of linseed-oil and one part of the alcoholic sublimate solution. The peritoneal cords thus prepared had been used experimentally for the ligation of large vessels in animals and as a suture material in the clinic, and had always given great satisfaction. As compared with catgut it presented the advantages of being finer, stronger, more flexible, and more easily sterilized. Culture experiments with the prepared peritoneum had always given negative results, which was more than could be said for most specimens of catgut in the market.

Wounds of the Pericardium.—Dr. Amerio, of Cagliari, reported a case of wound of the pericardium, the heart having escaped. The most prominent symptoms presented by the patient were dyspnœa, small, rapid, and irregular pulse. From two of the seven wounds in the præcordial region pericardial fluid mixed with blood issued, and percussion showed an increased cardiac area and pneumo-pericardium. Treatment consisted in enlarging the wounds, disinfecting the pericardial cavity, and then closing the wounds with an antiseptic dressing. The author referred to the reports of similar cases in literature, and to instances of puncture or incision into the sac in certain forms of pericarditis, and endeavored to fill the gaps now existing in surgical literature concerning the symptomatology and curative processes in wounds of the pericardium not involving the heart. He had made numerous experiments to this end on rabbits, making in some cases a simple incision into the pericardium, in others practising a partial or total ablation of the sac. Except for two cases in which death occurred from infection independent of the operative procedure, all the animals survived the infliction of the trauma. The following were the conclusions derived by the author from the results of his experiments: 1. Animals may live in apparent health even after wounds which have resulted in complete pericardial adhesions. 2. Pericardial surgery should be further developed, so as to render certain the prevention of septic infection and of wounds of neighboring organs. 3. In cases in which it is certain that the pericardium has been wounded, especially if the lesion has been made with septic instruments, surgical intervention is justifiable; it should consist in enlarging the pericardial wound, washing out all blood and pus from the sac, and thoroughly disinfecting it. 4. In certain cases also of thoracic tumors which have invaded the pericardium, one may remove the affected portion of the sac without prejudicing the life of the patient.

Repair of the Bladder after Gunshot Wounds.—Dr. W. Stankiewicz, of Warsaw, reported a case of wound of the bladder from a pistol-ball $\frac{7}{25}$ inch in diameter. The fifth day after the injury the patient had retention of urine from obstruction of the urethra by the projectile,

which had been passed spontaneously from the bladder and had lodged in the fossa navicularis. The ball was extracted, and the patient was completely cured eight days after the accident.

Sarcoma of the Bladder Discovered by Means of the Cystoscope.—Dr. Stankiewicz also reported a case of sarcoma of the bladder the size of a cherry, the diagnosis of which could not have been made without the aid of the cystoscope. The only symptom of the condition was an intermittent hæmaturia. The tumor was extirpated, and no relapse had occurred a year after the operation.

Operative Treatment of Congenital Dislocation of the Hip.—Dr. A. Hoffa, of Würzburg, said he had now performed the operation devised by him for the correction of this deformity seven times, with perfect results. In patients over ten years of age, the head of the femur is often so deformed that this operation would offer little promise of a cure. In such cases he advised an operation for obtaining bony union between the femur and the iliac bone, the opposing surfaces being denuded and held in contact by a retentive splint. He had obtained very satisfactory results from this procedure.

Treatment of Congenital Dislocation of the Hip.—Dr. A. Paci, of Pisa, treated this condition by certain manipulations, consisting in, 1, flexion; 2, abduction; 3, external rotation; and 4, slow, graduated, and progressive extension of the thigh on the pelvis.

Infection Following Open Fractures.—Dr. D. Roncali, of Cagliari, read a paper with this title, in which he related a number of experiments made upon animals to determine what forms of infection follow open fracture. The following were the conclusions based upon these experiments: 1. Compound fractures left untreated not only never heal, but lead invariably to the death of the animal. 2. Blood-poisoning in these cases is caused by one of the following micro organisms: Bacillus œdematis maligni, bacterium coli commune, bacillus pseudo-œdematis, staphylococcus pyogenes aureus, and streptococcus septicus. 3. The pathological changes found in animals dying after compound fracture of the femur are the following, in the order of gravity and frequency: *a*, medulla of the fractured femur (myelitis, acute, chronic, and suppurative); *b*, liver (hepatitis, degeneration of the tissue, and limited necrotic areas in the viscus); *c*, kidneys (nephritis, necrosis of the epithelium of the straight tubes and of the loops of Henle, etc.); *d*, spleen (acute and chronic splenitis, destruction of the giant-cells of this organ); *e*, lymphatic glands and vessels (suppurative adenitis and angioitis, hypertrophy and hyperplasia of the glands); *f*, periosteum and joints (acute, suppurative, and chronic periostitis and synovitis); *g*, muscles (acute and chronic inflammation, degeneration, and necrosis of the muscular fibres); *h*, lungs, heart, and brain (inflammation and lesions resulting from embolism and thrombosis).

Hard on the Employees.—"The following notice is posted in the Pension Office at Washington: 'Members of the medical division are forbidden to have their hats or clothing on preparatory to leaving this office before four o'clock. Any one breaking this rule will be charged with a demerit of fifteen minutes.' It is perhaps not strictly our business, but we should think it would be rather uncomfortable for the clerks of the medical division to work all day without any clothing."—*New York Tribune.*

"Such an order would make one believe that the pension employees are decidedly 'in the swim.' It would be more appropriate on the door of a natatorium than on a pension bureau. This reminds us of Pat's reply when the Jew wanted to 'sell him a trunk to put his clothes in.' 'What,' said Pat, 'and go naked?'"—*Texas Medical Journal.*

"Or of Pat's wife, when her mistress asked her to serve the tomatoes 'undressed.' 'No,' said Bridget. 'I will lave the place before I will do it.'"—*National Medical Review.*

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

ROYAL MEDICO CHIRURGICAL SOCIETY—VESICAL HERNIA—INTRA- AND EXTRA-PERITONEAL CASES—CLEFT OF HAND AND SOFT PALATE—CLINICAL SOCIETY—MYOCARDITIS—SPLENIC ABSCESS—FRACTURES OF TIBIA AND FIBULA—MEDICAL DEFENCE UNION—CHELSEA HOSPITAL FOR WOMEN—STATUE TO SURGEON PARKE—NURSES' RIVALRIES—MEMORIAL TO LIVINGSTONE.

London, April 28, 1894.

The contents of a hernial sac are sometimes different from the anticipations of the surgeon, and since radical cures have been more frequently attempted accidents have occurred during operation. A number of cases are known in which the bladder has been perforated. On Tuesday last a case was brought before the Royal Medical and Chirurgical Society, in which what appeared to be an empty sac was tied and cut away, the stump being returned to the abdomen and the inguinal ring closed. Next day, hypogastric pain and bloody urine led to the abdomen being opened, and the wounded bladder sutured; for an extra-peritoneal diverticulum had been taken for the empty sac. I believe this is only the sixth case of this form of vesical hernia recorded, though there are many in which the intra-peritoneal form has been met with. This hernia seems to give rise to no special symptoms, and the structure is not easy to recognize, so that only the utmost vigilance on the part of the operator can prevent accident. In fact the bladder has in most cases been wounded.

The presence of the bladder in an inguinal hernia, as in this case, is rare enough, but still more uncommon is the complication in femoral hernia. Nevertheless a Fellow of the Society gave some account of a case in his practice. It occurred in a woman, aged sixty-seven, the subject of hernia for seventeen years. The bladder was injured, but the patient made a good recovery. It was suggested that the neck of every thick sac should be traced back to the point of origin of the thickening, and that if the finger be passed along the neck into the ring, the intra-peritoneal form of vesical hernia would probably not escape detection.

Another speaker said that in most cases he believed the hernia was neither intra- nor extra-peritoneal, but a mixture of both forms.

A paper was then read by Mr. Davies-Colley on a method of closing the hard and soft palate for clefts. The method is a modification of the plan published by the author more than three years ago, and the modifications have been in use for about a year. Some remarks were made on points of detail, and it was urged that in these cases operation should be done early.

Besides the subjects mentioned in my last as discussed at the Clinical Society's last meeting, Dr. Maclaren brought forward three cases of inflammation of the muscular tissue of the heart without affection of the endo- or peri-cardium. The cases occurred in acute rheumatism, and the absence of physical signs was dwelt upon, especially delirium, which is symptomatic of myocarditis in the absence of pneumonia or pericarditis. No doubt this complication has been recognized as one which may be met with, but it is so constantly accompanied by endo- or peri-cardial inflammation giving rise to physical signs, that in the absence of these it might be overlooked.

Dr. David W. Findlay then related a case of splenic abscess, with secondary abscesses in the liver, in a girl of twenty. Three months previously she had suffered from pleurisy, and on admission to hospital it was supposed that this had recurred. Pyæmia supervened and she died. There was no history of injury, and the origin of the affection could not be traced. At the autopsy

ulcerative endocarditis was found, and the spleen was one and a half time its normal size and fixed to the diaphragm by adhesions; there were also two small abscesses in its upper part and extensive pleuritic adhesions.

Mr. Arbuthnot Lane next read a paper on the operative treatment of simple fractures of the tibia and fibula in certain classes of laborers in whom he estimated that the depreciation of the workman's value by this injury sometimes amounted to seventy per cent., and often meant ruin to him. In consequence of the alteration in the lines of pressure through the joints, pain and insecurity are felt and progressive mechanical arthritis results. Mr. Lane therefore cuts down on the fracture, removes any soft parts or fragments of bone in the way, and brings the surfaces accurately together by traction on the foot, by elevators, and holds the parts in apposition with lion forceps, till holes have been drilled and the bones fixed by steel screws. This proceeding, he said, relieves the patient at once from pain and discomfort due to movement of the fragments or extravasation between them. It also shortens the duration of the man's incapacity to earn his living, as bony union is rapid and the mechanism of his skeleton restored to its state before his accident. He read notes of three cases operated on in the same week, and supplemented these by brief notes of forty cases collected by Mr. Stewart. In the discussion that followed attention was drawn to the risk incurred by converting a simple into a compound fracture, and some doubt was expressed as to whether the results in ordinary cases were as serious as Mr. Lane represented.

The Medical Defence Union seems to be in some danger of falling to pieces, unless the members take some vigorous steps to prevent this. Upward of a hundred have signed a requisition for convening a special meeting to consider the recent action of the council, and, if thought fit, to repeal some of the articles of association and substitute others preventing the council or governing body from acting as they have done in certain cases.

The Committee of Inquiry into the allegations against the Chelsea Hospital for Women is being reorganized, and although the consulting officers have declined to serve, there is a prospect that the inquiry will be satisfactory to the public and to the profession.

The memorial statue to Surgeon Parke, of the Emin Expedition, is to be of colossal dimensions, and will represent him in a costume suitable for African exploration. It will be supported on a pedestal having a bas-relief of Dr. Parke engaged in his professional work on some striking occasion during the expedition.

Nursing associations have their little rivalries and separate organs, which sometimes indulge in imprudent observations. At any rate, the *Nursing Record* seems to have done so and has been promptly sued by the Royal Pension Fund for Nurses, and has to pay forty shillings and costs.

Mr. H. M. Stanley on Saturday last laid the founda tion-stone of a Cottage Hospital at Dartford, dedicated to the memory of Dr. Livingstone.

THE LATE PROFESSOR BROWN-SÉQUARD.

To the Editor of the Medical Record.

Sir: I wish to say a few words concerning the late Dr. Brown-Séquard, and to point a moral. He occupied the Chair of Physiology in the Medical College of Virginia in 1854. At that time he was incapable of lecturing in English, but his most beautiful demonstrations were patent. Probably for the former reason he was retained only one session. The school of the French physiologists was then at its zenith, and we owe more physiological knowledge to them than to all the world besides. Bernard was first and Brown-Séquard second in fame.

Brown-Séquard's ardor for vivisection was unbounded, and many laughable scenes were the consequence. On one occasion his assistant for some reason let go the cat, which immediately vaulted to the devoted head of the professor, "snatching him bald-headed," and clawing his face, getting the first blood. But the man who would stand before the class and let down pieces of sponge into his stomach, like one fishing for crabs, could not be deterred by such a trivial matter. Accordingly, albeit his wig was off, he rushed around the room and over the benches after grimalkin, finally caught her, and most conclusively demonstrated to the convulsed class that a section of the cat close to the medulla oblongata produces, first, convulsions, and then death.

The basement of that graceful Egyptian pile, the college, presented the appearance of a bench show. The guinea pig, the favorite of the French physiologist, was not present.

The epileptic owes an everlasting debt of gratitude to this famous savant, for there is nothing so efficacious in epilepsy as the bromides; chloral is a superior remedy for exclusively nocturnal epilepsy. He taught that there is "a positive relation between the intensity of the bromide eruption and the efficacy of the remedy."

Brown-Séquard, with other physiologists, established the fact that the fibrine of the blood disappears while passing through the liver and kidneys. But for this fact the blood would coagulate in the vessels.

He gave a valuable point in hypodermic medication. The best time to give a hypodermic is when the patient is fasting; less medicine is required and the effect is greater.

His work regarding the spinal cord is known to every tyro in physiology.

These are but a few things which this honorable gentleman did. But, alas! some men live too long and impair their fame. His "elixir" was probably the outcome of senility, for he was seventy years of age when he announced the ignoble extract. He fancied that after he had received an injection of it into his loins he could run up and down stairs like a boy, that it also enabled him to do more and better mental work without fatigue.

Unfortunately, he gave the cue to younger men in our country, who should know better, and they have made extracts from nearly every organ in the body of the sheep or calf. But unlike the great and honest experimenter, they, presumably, follow in the wake of the alchemist; they would turn these baser elements into gold.

Their products are supposed to act upon the principle of the ancient doctrine of signatures, as lungwort and liverwort; or upon the principle that in order to learn to read a language it is only necessary to swallow the alphabet.

The humbuggery of such therapeutics was long since disproved by a paraplegic patient, who confided to me that he had been drinking his own urine in the hope that his system would reappropriate the mucus.

Thomas R. Evans, M.D.

Burlington, Ia.

MORPHIA PRE-NARCOTISM IN CHLOROFORM ANÆSTHESIA.

To the Editor of the Medical Record.

Sir: In a paper on "Depressed Fracture of the Skull," published in the Medical Record, April 28th, Dr. Dillon J. Spotswood says: "In administering chloroform it will be found that a hypodermic injection of morphia, gr. $\frac{1}{4}$, and atropia sulph. $\frac{1}{150}$, a half-hour before, *always* maintains the heart and respiration during chloroform anæsthesia." (The italics are mine.)

If such is the case, and if the heart and respiration never fail us after the above preliminary medication, we must then have in chloroform an ideal anæsthetic which should be used to the absolute exclusion of ether. I can hardly bring myself to believe that this is correct and should be very glad to have Dr. Spotswood furnish more detailed information on the subject.

Very truly,

Joseph Brown Cooke.

269 West 138th Street.

GOETHE'S REPORT OF A TOOTH IN THE NOSE.

To the Editor of the Medical Record.

Sir: Referring to the recent report[1] by Dr. Knapp of a case of tooth in the nose, I am reminded of having lately stumbled upon a report by Goethe of a similar case observed nearly a hundred years ago. It is well known that Goethe discovered, or first drew attention to, the presence in man of an intermaxillary bone. His passion for all sorts of scientific knowledge induced him, doubtless, to mention in his letters, written on a journey to Switzerland in 1797, the following case, a translation of which I take the liberty of sending you, as it may prove of interest to your rhinological readers. The letter is dated Stuttgart, September 6, 1797:

"After dinner I went with Dannecker to Rapp's, where I found a remarkable osteological preparation. A young woman whose brothers and sisters had been afflicted with diseases of the bones had herself suffered in chilhood severe pain when pressure was made on the upper jaw under the left eye. This tenderness gradually extended downward toward that half of the palate; a swelling occurred in that region and something hard could be felt in it. She lived for nineteen years and finally died of consumption. The part of the skull which they preserved after the autopsy presented the following points of interest:

"The left half of the intermaxillary bone contains two good incisor teeth. The canine tooth is lacking, and from the small alveolus one observes that it must have fallen out soon after the second dentition; then comes a molar tooth, then a small depression with a sharp border, but without an alveolus; then a large molar, and then a so-called wisdom tooth not quite fully developed. When the nasal cavity of the preparation is examined a very curious condition is noticed: a tooth is fixed under the edge of the orbit with its root fast to a little round rough mass of bone; it extends in its position directly downward and backward, and had apparently bored through the palatal part of the superior maxilla just behind the incisor canals, or rather the bone had become carious from the unnatural irritation of the parts and an opening is observed eaten out larger than the crown of the tooth. The crown remains only a little in front of the plane of the palate (sic).

"The tooth is not shaped exactly like the other molars; its root is single and long and its crown not so broad. It appeared, however, to be a sound tooth in active growth whose path toward its proper place was obstructed by the irregular and more rapid growth of the neighboring teeth, so that it had gone upward and backward and so caused the misfortune. Apparently it is the missing molar (?), of whose alveolus there is no trace to be seen. At first I was inclined to believe it was the canine tooth. If this condition had been suspected, I am convinced that the patient could easily have been operated on and the tooth removed; whether, with her unfortunate constitution, her life could have been lengthened by this is doubtful.

"It is to be regretted that only the interesting portion was removed, and that the other half of the maxilla, or, indeed, the whole skull, had not been preserved, so that the bony structure could have been observed in those parts which showed no striking irregularity."

Does anyone know of a better or an earlier report?

Yours, etc.,

Jonathan Wright, M.D.

Addison on Medical Advertising.—"Advertisements are of great use to the vulgar; first of all, they are instruments of ambition. A man that is by no means big enough for the *Gazette* may easily creep into the advertisements, by which means we often see an apothecary in the same paper of news with a plenipotentiary, or a running footman with an ambassador."—*The Spectator.*

NITRATE OF SILVER IN GONORRHŒA.

To the Editor of the Medical Record.

Sir: The article of Dr. John McGrath, in the Medical Record of April 14th, on the subject of nitrate of silver injections in deep urethritis, has induced me to relate my own experience. For a number of years I treated all cases of deep urethritis and gonorrhœal cystitis with injections of nitrate of silver, varying from the customary deep injection of a solution of from one to five grains to the ounce to large injections of very weak solutions, about six ounces at a time, the strength usually but one-eighth grain to the ounce. I also allowed the patient to empty his bladder of the solution after withdrawing the catheter.

These weak injections I have used many times, and the conclusion that I have reached is that all nitrate of silver injections, even of these very weak solutions, are liable to be followed by a violent reaction, prolonged spasms of the bladder with constant desire to urinate, and finally gonorrhœal cystitis and orchitis.

My catheters have always been carefully disinfected, have been inserted with the utmost gentleness, the solutions as above stated have rarely exceeded one eighth grain to the ounce, and yet I have often enough seen unfortunate results to warrant me in saying that, where we use even the weakest nitrate of silver solutions, we may do harm.

I recall one case where several injections were borne well with steady improvement, until one precisely similar was followed by orchitis and cystitis, with prolonged fever.

The cystitis and orchitis never follow unless preceded by the reaction and bladder spasm I have described, and I think it is the traumatism resulting from this, and not the cauterizing effect of the silver nitrate, that causes trouble. One can never tell when one will have this reaction, though nervous, irritable urethræ predispose to it. In some cases I have controlled it by cocaine injections into the bladder and ice to the perineum. I will not deny that no remedy will compare with nitrate of silver injections for treating deep urethritis and gonorrhœal cystitis, but it is nevertheless a very uncertain and dangerous remedy.

Creosote internally is lately giving me good results.

O. T. Freer, M.D.

288 East Huron Street, Chicago.

CERTAINLY NOT!

To the Editor of the Medical Record.

Sir: Will you kindly inform me whether the new code, about which so much controversy waged, was intended to permit consultations with homœopaths, or to permit specialists to meet homœopaths for the purpose of getting their patients away from them? Permit me to relate the following incident, of which I was an eye-witness.

A family, attended by a regular physician in whom its members had entire confidence, had the whim of calling in a young homœopathic physician in the neighborhood in case of any ailment judged by them to be trifling. On one such occasion, after a day or two of illness in an old lady, the homœopath, Dr. A——, decided that there was a strangulated hernia, and called in, without much discussion or deliberation but with permission from the son, a homœopathic consulting surgeon, Dr. B——, who advised an operation. Upon that the family, terrified, decided that they wanted another consultant, a well-known specialist, regular, and undoubtedly skilful, and moreover somewhat famed for his obliging readiness to meet homœopaths in so called consultation. A friend of the family, quite irresponsible in the matter, went for the specialist, Dr. C——, begged him to come to meet the homœopathic gentlemen, and on his own responsibility added he wanted Dr. C—— to operate. Dr. C—— came, met the two homœopaths, listened to their

account of the case, agreed entirely with their diagnosis and plan of operation, which were in fact correct, but then, as Dr. B—— was making his preparations, Dr. C—— slipped out of the room, to hold a private conversation with the patient's son. No one knows what here transpired; but the result was that the son, with that delightful pliability under the moulding hand of the last comer which habitually characterizes the friends of patients, promptly dismissed Dr. B——, with scant courtesy, leaving Dr. C—— the field, the fees, and the operation. Now if a consultation means anything, it means that the consultant intends to meet a practitioner fairly and deal with him loyally; that he is to protect him from the officious meddling of outside friends, and only rupture with him if there arise an irreconcilable difference of opinion, upon which an appeal for choice may be made to the family. But to profess to meet them, to be compelled in a given case to agree, and then to so pull the wires of family fears and susceptibilities as to get the case into one's own hand, seems to me an utterly indefensible proceeding, and I should be glad to know how such cases are viewed by the RECORD.

FAIR PLAY.

MUST THE PARSON PAY?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your editorial in the issue of April 21st about the parson paying his medical bill no doubt struck a responsive chord in many a doctor's heart. Many of us, many times, have thought they should pay, but hardly knew how to start about it. In the days of Auld Lang Syne, when the preacher travelled many miles every week and preached many sermons, going on horseback probably, with his wardrobe and bookcase in his saddle-bags behind him, and having no earthly possessions, singing as he rode, "No foot of land do I possess," etc., it certainly would have been, and was, a great pleasure for doctors to give them all needful medical attention free of charge. Then they were objects of charity indeed, but the times have changed. In our cities and larger towns the parson is now quite a different man. He rides no longer on horseback. Now steam carries him when going to a distant place, and a coach when he travels close to his home. Many do their pastoral work easily by walking, and the majority of them command good salaries. My town (Durham, N. C.) has a population of about eight thousand. We have some fine churches here as well as large tobacco factories, cigarette factories, etc. Our preachers, generally speaking, are well-paid men. For years I have been a member of the church, and for years have done the practice of the ministers of every denomination free of charge, while, at the same time, I was assessed freely for the support of my ministers, both active and superannuated. For twenty years I have practised here, and for twenty years have never charged one cent for my services to ministers; but I have had compunctions of conscience about the matter. I argued thus: Our salaried men are the best-paid men in our community. How can a salaried man expect a non-salaried man to do his work for nothing, especially as the latter is taxed for his support? I determined to quit it.

This year we had a new minister sent to our church. I approached him and remarked: "Brother ——, you will get a handsome salary this year, the parsonage is fitted and furnished for your family without charge to you, and I advise you, whenever you call a physician, to pay your medical bill." Not long after this he came to my office and asked me to call and see his daughter. I then told him again that I should charge him for each and every visit made, and went to see his daughter.

At the beginning of each year our assessments are read out, and when objections were called for I arose and increased my assessment from $39 to $50 per year. At the next meeting of our medical society I told the Academy of my action, and asked that they would give me the privilege, if they did not indorse my action, to charge ministers of all denominations. They not only said they would give me the privilege, but we passed the following law in substance, viz.: That after this date ministers of all denominations would be charged as per the following: All ministers receiving as much as $500 per annum would have to pay one-half medical rates, fifty per cent. All ministers receiving $1,000 and above would have to pay full fare, or the regular medical charges. I suppose those receiving less than $500 will get their services free of charge. What will be done with the money received from such sources I cannot say, but rather believe the doctors will turn it over to some charitable organization here in Durham.

Now a few further remarks and I am done. The doctors (Israelites) have been in bondage to the ministers (Egyptians) more than four hundred years. The yoke, which was light at one time, has become burdensome now. Some of us (Durham doctors) have rebelled and rather like the change. We propose to continue our rebellion. Why, some of these very ministers for whom we have worked and labored for nothing, and for whose support we were assessed, have left us for other fields of labor, and never said even "Thank you"—yea, more than that, they have gone about while here doing pastoral work, and have recommended patent medicines and proprietary nostrums—yea, more than that, still, you can pick up the newspapers and see their names, standing out in bold relief, as the Rev. Mr. So and So, patronizes and indorses such and such patent medicine or humbug instrument. His wife was cured, he himself mightily helped, and his child never would have lived had it not been for one of these patent abominations. *O tempora, O mores!* Now, Mr. Editor, let the doctors kick themselves. They are more than half responsible for this state of affairs. Let there be a widespread uprising of medical men against this more than Egyptian bondage, and you may count on Durham, N. C., doctors as being always in front, as they have already raised the battle flag and intend to beat down all opposition, or fall with their faces to the enemy. They are battling for the right.

Yours with esteem,

A. G. CARR, M.D.

DURHAM, N. C.

PERMANGANATE OF POTASSIUM IN OPIUM POISONING.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the issue of April 14th of your esteemed journal Mr. L. A. Harding, B.Sc., Ph.D., of Fergus Falls, Minn., expresses grave fears that boiled starch might interfere with the antidotal power of permanganate of potassium, for in his opinion boiled starch in any form quickly demands its attention. I fail to understand how Mr. Harding could have made such a statement, for the most superficial test will show that the reaction between boiled starch and $Mn_2K_2O_8$ is much slower than the reaction between the latter and albuminous matter; consequently boiled starch cannot come in consideration at all as a rival of morphine in deoxidizing the new "supposed" antidote.

Mr. Harding furthermore claims that the decomposition of the permaganate in an alkaline fluid proceeds but very slowly.

Now I found that its decomposition in an alkaline solution of albumen is just as rapid as in a neutral solution of the latter. Will Mr. Harding kindly give me the satisfaction to state what kind of soluble organic substance he has used when "a test-tube full of water containing soluble organic substance which had been made alkaline, and to which had been added a few drops of a solution of potassium permanganate, did not begin to discharge its color for nearly an hour"?

Mr. Harding calls my advice "to give an acid of some kind in case of opium poisoning, or in case of any of the salts of morphia," erroneous beyond measure; for do not text books teach, and experience has proven, that acetic

acid especially decomposes permanganate? I have never advised to give an acid of some kind in case of poisoning with any of the salts of morphia, but have done so only with regard to poisoning by the alkaloid morphia itself (not its salts) or by opium and its preparations.

The fact that "text-books teach that acetic acid especially decomposes permanganate" is no argument against my advice. While we never should cease to be students, yet it would be puerile to be hampered in independent investigation by remaining slaves to "text-books!" In my first article on the subject in question,[1] I have said verbatim: "In cases of poisoning by the alkaloid itself or by tincture of opium, also by opium, it is advisable to acidulate the antidotal solution with diluted sulphuric acid, or in the absence of this with some white vinegar (not red vinegar), by which the insoluble morphia will be at once converted into the soluble sulphate or acetate."

How such an advice could be called "erroneous beyond measure" is to me incomprehensible beyond measure. Everybody can easily convince himself that diluted sulphuric acid does not deoxide permanganate at all, and that the latter is acted upon so feebly and slowly by diluted acetic acid that its antidotal power cannot be lessened through the addition of some white vinegar. The addition of fifteen drops of diluted acetic acid to one ounce of water imparts to the latter a distinct vinegar taste; one drop of a 1 to 15 $Mn_2K_2O_8$ solution is decolorized by this acidulated water only after prolonged stirring and shaking; two or three drops of the same solution impart to the ounce of acidulated water a purplish color without changing its vinegar taste. When we consider the fact that two drops of diluted sulphuric acid are sufficient to convert one grain of the insoluble alkaloid morphia into the soluble sulphate, it is evident that under ordinary circumstances in cases of poisoning by laudanum or opium it is sufficient to add one teaspoonful of diluted sulphuric acid or white vinegar to six or eight ounces of the antidotal solution. It is rather a peculiar coincidence that my first case of supposed morphine poisoning, which I treated successfully by potassium permanganate without using diluted sulphuric acid or diluted acetic acid proved to be a case of poisoning by sixty to seventy grains of powdered opium. While I am very well satisfied with the results obtained, yet I should not have hesitated to use one of the diluted acids above mentioned had I been aware of the exact nature of the case. I shall be happy to give the profession an account of the case referred to, together with a synopsis of other cases that were reported to me, and trust it will turn scepticism as to the efficacy of permanganate of potassium as an antidote for opium into faith in its usefulness for the purpose stated.

WILLIAM MOOR, M.D.

355 BOULEVARD, NEW YORK, April 26, 1894.

Alliteration was a favorite form of literary expression among the early Saxon poets, but its use in modern times has been very limited, perhaps because this special form of talent has not been encouraged and therefore has not developed. St. Louis, however, has a writer who exhibits a remarkable capacity for alliteration as well as for historical imagery. Of one eminent Louisville surgeon the editor of the *Medical Mirror* says, after half a page of deluging compliments: "Truly he is the prancing, princely, playful, peerless, popular, passionate, peace-loving, persuasive, picturesque, piquant, pushing, polished, puzzling, palm-taking Palmer, the superb." The doctor's capacity for alliterating with the initial "p" is not exhausted by the above; for he says, "I am sustained, and more than sustained, by the bright, bold, broad, and brainy Bauduy, the piquant, polished, persuasive, pungent, pink of perfection in the psychiatrical pasture." A gentleman is also described as "the eloquent, erudite, earnest, emphatic, energetic, Stephen A. Douglas of the St. Louis Medical Society."

[1] MEDICAL RECORD, February 17, 1894.

New Instruments.

DR. L. JANKAN'S ACOUSTICON.

BY A. ROSE, M.D.,

NEW YORK.

THIS contrivance is constructed on physiological principles to imitate the natural ear, whereby all the advantages found in instruments already in use, as the inventor claims, were considered and applied.

The instrument consists of a sound-bell (*S*) tapering into the processus (*a*), which is to be inserted into the ear. The sound-bell itself consists of the part (*r*) and a funnel-shaped insertion (*t*), the latter provided with a curved membrane (*m*). Part (*r*) corresponds with our antitragus (*at*), part *T* with our tragus; the membrane (*m*) with our tympanum; everything magnified, so to say, idealized. Part (*r*) is to collect sound waves and to throw them on the tympanum, at the same time to prevent the escape of sound-waves. Sounds enter thus the ear without echo, that is, without concomitant, disturbing noise.

Processus (*a*) is to be inserted, air-tight, into the ear of the patient. Dr. W. Vulpuy, who examined the instrument when I demonstrated it before the German Medical Society of this city at the February meeting, and who has tried it on some of his patients, suggested an additional rubber attachment to this processus, in order to secure a better fitting insertion. But this would interfere with the advantage so important in certain cases of an osseous conduct, which the unarmed processus inserted into the meatus offers, and which is the main feature of a number of hearing appliances.

To transform the instrument into a speaking-tube, by means of which a whisper may be understood, we notice at the processus (*a*) two openings (*b*, *b*), which otherwise are closed by means of stoppers, to which otoscopes (*c*) can be fastened. When the otoscopes are attached the opening (*e*) is to be closed air-tight. If only one otoscope is to be used, it is to be connected with the opening (*e*), while the openings (*b*, *b*) have to be closed.

In this form the instrument is of good service when patients apply it while in church, theatre, concert, etc. It can be turned toward the source of the sounds, and thus applied it is little noticeable.

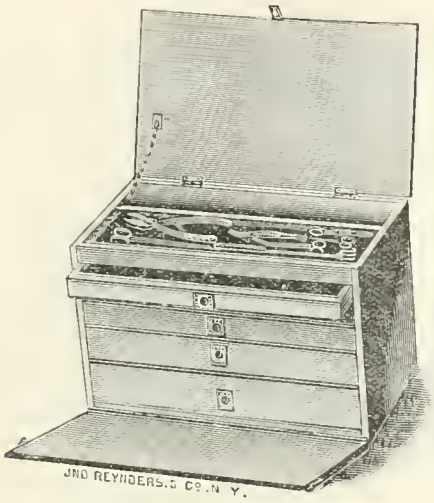
In many cases of defective hearing the cone (*t*) with its membrane is to be removed, either for a while or for good.

I, as well as all the gentlemen to whom I gave the instrument for trial, had very gratifying results.

215 SECOND AVENUE.

PORTABLE OPERATING CABINET.[1]

BY R. HARCOURT ANDERSON, M.D.,



NEW YORK.

PHYSICIAN TO THE NEW YORK LYING-IN HOSPITAL, ETC.

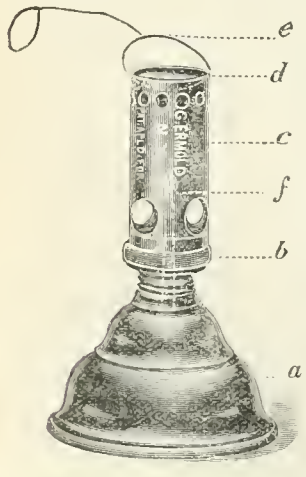
WELL knowing the difficulties under which the ordinary surgeon labors in transporting instruments, and more especially the accessories appertaining to the proper performance of a surgical operation of any importance, and also being cognizant of the very inferior accommodation existing in the average private house for surgical work, I was led to devise the cabinet herewith presented. It is simply, to speak plainly, a cabinet of wood, adapted to the exigencies of surgical work of the extra hospital kind, and consists, anteriorly, of a row of drawers in which the

[1] Presented before the New York County Medical Association.

instruments are placed, while posteriorly is a chamber most useful, for in this can be placed almost all irregularly shaped articles, such as very large bottles, rubber sheets, Kelly pads, etc.—to be more comprehensive, all those surgical appliances which do not readily fit in a leather bag or case. (Vide illustration.)

Each drawer is lined with a soft material, which in this case is ordinary lint, which of course is "replaceable" and washable. The cabinet is practical, cheap, and will answer the twofold purpose of office or outside work. Members of the profession, especially the younger ones, and those residing in the rural and suburban districts, will undoubtedly find it more or less serviceable. The cabinet can be obtained from Messrs. Reynders & Co., of this city.

38 West Twenty-first Street.

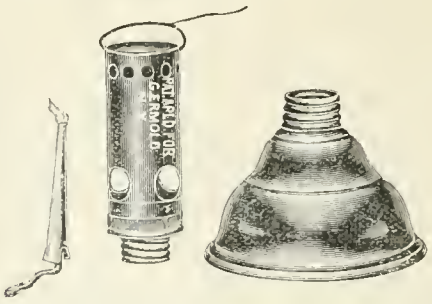


A NEW, SAFE, AND SIMPLE APPARATUS FOR SUBLIMING CALOMEL IN THE TREATMENT OF DIPHTHERIA AND SCARLET FEVER.

By DILLON BROWN, M.D.,

NEW YORK.

This calomel sublimer, made by George Ermold, 312 East Twenty-second Street, New York, has the advantages not only of being simple and convenient, but also of being absolutely safe from danger of fire or explosion, and of being economical in the use of alcohol, burning less than one-third as much as the ordinary lamp.



It consists of: 1. An alcohol cup (*a*) which is filled with asbestos to prevent any liquid from escaping should the lamp be upset; and its shape is such that no alcohol can run out, even should the asbestos be oversaturated with it.

2. A chimney (*c*) which protects the flame. It has air openings above and below; and at the top is a shallow pan (*d*) to contain the calomel which is to be sublimed. A flexible wire (*e*) is fastened to the upper end of the chimney, so that the whole apparatus can be suspended, if more convenient, under the croup tent.

3. An asbestos washer (*b*) which separates the alcohol cup from the flame and the chimney, thus preventing the heat from reaching the alcohol and causing it to run over and set fire to the surroundings.

4. The wick (*f*) which reaches high enough in the chimney above the lower air-openings to prevent any danger of fire from this source.

5. Each outfit contains one ounce of the purest calomel, divided up into compressed tablets of ten grains each.

Medical Items.

Leprosy	0	0

Diphtheritic Paralysis.—Diphtheritic paralysis generally manifests itself from eight to fifteen days after recovery from the local symptoms, though it may be delayed to a later period; in very exceptional cases it has been observed during the first week. This paralysis exists in one-third of the grave cases, according to Rogers's statistics; it is not a rare sequel of benign diphtheria. The onset is generally slow and insidious. There is first only a little hesitation of the motor functions; deglutition, walking, and other movements become more and more difficult. The place of election of the paralysis is the velum pendulum, where it generally begins, and where it sometimes remains localized. A slight pallor, a little slowing of the pulse, are the only disturbances of the general state which are then noted. The reflux of liquid aliments by the nares indicates the impediment to deglutition. Extension of the paralysis to the pharynx generally supervenes, and the food can only be swallowed after repeated attempts, which soon fatigue the patient, and sometimes result in the refusal to take nourishment. Loss of voice testifies to paralysis of the larynx. The muscles of the eyes, of the neck, of the trunk, of the upper and lower extremities, of the rectum and bladder, even the special senses, are taken in the more complete forms of paralysis. More rarely the paralysis will attack the lower limbs before affecting the larynx and the tongue; and in a few cases it has been known to begin with the arms, then invade the soft palate and œsophagus, to attack finally the lower extremities. It is a common experience to see troubles of vision supervene which are attributed to a fault of accommodation. The sight is enfeebled in different degrees, which may vary from slight amblyopia to complete blindness; there is hypermetropia, mydriasis, and, if but one eye is affected, inequality of the pupils. Almost all of the eye-muscles may be affected in turn. The lower extremities generally begin to be paretic when

these ocular troubles exist. The paralysis of the legs generally assumes the form of an incomplete paraplegia. It is announced by formication and numbness in the legs. Walking becomes uncertain; the patient has an incomplete perception of the ground under his feet, and finds it especially difficult to go up and down stairs, or walk in the dark. A peculiarity of this form of paralysis is that the loss of motility in the feet and legs is never complete; the patients can move along by dragging or sliding their feet. When they are confined to their bed the lower limbs still preserve considerable power of movement, but without energy or much certainty. Jaccoud calls it an ataxy of movement, rather than paralysis. These ataxic symptoms, in conjunction with the abolition of the patellar reflex and the eye troubles, may give rise to a form of pseudo tabes. Contracture is very rare. The affected muscles present the ordinary reaction of degeneration; there is augmentation of the galvanic and diminution of the faradic contractility. With regard to the condition of the hands, these become awkward and clumsy; patients drop or upset objects which they attempt to handle; tremblings resembling the tremors of paralysis agitans are frequently present. The muscular enfeeblement may be so great that the patient cannot feed himself.

Paralysis of the face is a rare phenomenon. Bourges, who has written a very complete description of the diphtheritic paralysis, and from whom we have here borrowed, gives a graphic account of cases which he has witnessed, when the syndrome of labio-glosso-laryngeal paralysis was perfectly reproduced; the tongue, lips, cheeks, larynx being simultaneously affected. Troubles of the sensibility are very frequent in diphtheritic paralysis, and almost always have to do with the regions affected with akinesic troubles. The ordinary alteration of sensibility is anæsthesia; exceptionally there is hyperæsthesia, which manifests itself in the lower limbs by numbness and formication, and generally precedes the akinesis. Frequently the anæsthesia when it exists does not extend above the knees and elbows, but it may be general. It is sometimes accompanied with analgesia so complete that cutting operations have been performed without ether. The anæsthesia may affect the lips, tongue, and cheeks, and in rare cases the special senses, hearing, smell, and taste, have been abolished. The speech is often hesitating, stammering.

A capital fact in diphtheritic paralysis, says this same writer, and one that distinguishes it from all other paralyses by peripheral neuritis, is that there is no muscular atrophy; the paralyzed limbs always retain their normal aspect and volume. In very rare instances the velum pendulum is not affected, and the disease is located in one muscular group or region without affecting other groups or other parts. Such are the cases where the paralysis has taken the paraplegic or hemiplegic form, where it is limited to the eye-muscles, to an arm, a leg, a hand, etc. Cases complicated with diaphragmatic paralysis are especially dangerous. In the localized and partial form the paralytic accidents may be transient, and disappear in a few days. When the paralysis is general, its course is slow, lasting sometimes weeks and even months. Diphtheritic paralysis generally terminates in recovery (eight times out of ten, according to Bourges). In favorable cases, the power of movement reappears first in the lower limbs, then in the throat, then in the arms and hands, the trunk, the viscera, and the eyes. Generally the organs to be first paralyzed are the first to get well, but there is no fixed rule even here, and it often happens that the velum pendulum is the first part to be affected, and the last to resume its functions. We have said nothing about those forms of infectious paralysis in which the heart and respiratory muscles are affected. These varieties are much more grave, for death then occurs often from syncope or asphyxia. These paralytic results of diphtheria have been reproduced in animals in the experiments of Roux and Yersin.—*The Boston Medical and Surgical Journal*

Motion of Human Spermatozoa.—Various authorities state that the spermatozoa may continue to move during twenty-four to eighty-four hours after death in the fluids of the seminal tract. Outside the body the movement of spermatozoa has been observed for seventy-two hours by Hofmann and Mantegazza for four days at a suitable temperature. Mr. Piersoll now states that at a temperature of 8.5° C. a few of the elements showed movement, after being kept for nine days. These facts show that spermatozoa may long retain their vitality in the female generative tract and must receive in future due consideration in connection with certain medico-legal questions.

Turnip as a Substitute for Decalcified Bone in Intestinal Surgery.—Dr. Baraçz, seeking a substitute for decalcified bone plates, which take too long to prepare, examined various vegetable substances and came to the conclusion that turnip is the best material for the purpose. (*The Medical Age.*) He performed a series of experimental operations on dogs, and among six gastro-enterostomies there were five recoveries, one dying of peritonitis caused by the escape of the contents of the stomach into the peritoneal cavity at the time of the operation. Among three cases of resection of the intestine there was one death due to intestinal occlusion consequent on the anastomosis being made too far from the sutured end. He considers the failures had nothing to do with the turnip plates. In a case of gastro-enterostomy which proved fatal, the seat of anastomosis was examined two days after the operation, and the plates found at the points where they had been applied, fixed by sutures around the fistula; the stomach-plate was soft like boiled carrot, the intestinal plate somewhat harder. Two dogs were killed fifteen to twenty days after gastro-enterostomy, and the plates found neither at the seat of anastomosis nor in the intestinal canal; the sutures had also disappeared. Neither was any trace of plates found in cases where the dogs were sacrificed at a later period—namely, thirty-eight to fifty days after the operation.

Recent Progress of Cremation.—The carefully prepared address of Bishop Lawrence before the Massachusetts Cremation Society, favoring urn burial, will do much to promote that reform, the advocacy of which has, unfortunately for its progress, been largely by persons of no religious faith or heavily charged with eccentricities. Not all men are scrupulous as to their lives, but most of us are strangely insistent that our death and burial shall be according to approved forms. The indorsement of the burning of the dead by a respected bishop will incline many more kindly to that sensible method. Very few persons actively oppose cremation. Most men are attracted to it, though not sufficiently interested to lend active aid. What the movement just now needs is its deliberate choice as a method of burial for themselves of persons so specifying in their wills. A few thousand men and women of commanding position in all lines of life who should publicly agree to such disposition of their remains after death would set a mighty precedent and pave the way for general acceptance of the practice. The objections to the early burnings—the escape of noxious exhalations and the defilement of the ashes with foreign substances—have been obviated through the combined inventive skill of Siemens and Sir Henry Thompson. Every consideration of sanitary science, economy, and a refined sentiment favors the reform; tradition alone blocks the way. The burying-ground is unquestionably a source of peril in every closely populated community, and the financial burden imposed upon the poor by the modern funeral is a grievous one. The task of the cremationists is to hammer away, until the absurdity of objections is manifest and the practice becomes so common that no moral courage is required to publicly approve it or engage in it. And the reform is making headway. Whereas in 1881 there was but one cremation society in the United States, there are now thirty five; and crematories are in useful operation in all the larger cities of Europe.

Indiscriminate Use of Prescriptions: An Encouragement to Quackery.—A correspondent sends the following communication to the *British Medical Journal:* "There can be no question of the fact that the medical men who give prescriptions to their patients do an enormous amount of financial injury to themselves and the profession, and by that means encourage quackery. The chemist who makes up the prescription easily finds out the symptoms, and applies the same treatment to patients of his own. He often repeats the medicine, saving the expense of a second visit to the consultant. Many patients are very fond of experimenting on others, and obligingly hand their prescriptions to their friends who have similar diseases as rheumatism, neuralgia, etc., thus causing a considerable loss to the profession. The obvious remedy for this is either to dispense one's own medicines or employ a reliable dispenser, and on no account give a prescription to any patient. These should be guarded as 'professional secrets,' which the public have no right to know, as often in the hands of ignorant people they do an incalculable amount of harm. Considering the present overcrowded state of the medical profession, and the abominable manner in which the public 'are swindled by prescribing herbalists' and advertising quacks, it is absolutely necessary that a special Board should be formed called the Society for the Suppression of Illegal Practice, whose sole duty should be the prosecution of all quacks with the utmost rigor of the existing law; that it is a paramount duty of every 'qualified man' to subscribe to such a fund, not only for his own interest but for the protection of the public. All newspapers should contain notices warning the people against the evils of quackery; and leaflets to this effect should be printed and distributed among the people at the expense of the society."

The Bacteria of Peritonitis.—The interesting subject of the bacteria associated with peritonitis has received a new and important contribution in a monograph by Drs. Tavel and Lanz. The authors have given in this report the results of their study of seventy odd cases of inflammation within and about the peritoneum or neighboring organs. But only a part of this number fall within the usual acceptation of the term peritonitis. The material for this study, with the exception of a very few cases, has been obtained at operations in the clinic of Professor Kocher, and has, therefore, the great merit of having been secured intra vitam, thus excluding the possibility of a post-mortem migration of intestinal bacteria into the peritoneum, a possibility which has been brought forward as an objection to the results of E. Fränkel and Predöhl in their work on peritonitis. The cases have been of the most varied character and diverse etiology; but if considered analytically they may be fairly well divided into several groups. In considering the bacteria met with in their examinations we shall only mention those which are recognized as having pathogenic significance, and shall neglect the less important forms, of which as many as a half-dozen or more species have been observed occurring together in some cases. Perhaps the most important class of cases are those in which there is inflammation in or about the vermiform appendix. Of these, nineteen cases were studied. The results may be given as follows: Of seven cases of purulent formation within the appendix, the bacillus coli communis was found in six, the streptococcus in two, and the pneumococcus in one case. None of the cases were sterile. In fifteen cases of peri-appendicitis, the examination of the exudate or abscess showed the presence of the bacillus coli communis in eight; the streptococcus in five; the staphylococcus citreus in one; the pneumococcus in one, and actinomyces in three cases. Two cases were sterile. The number of species found varied in the different cases from one to nine in number. It is interesting to note that the examination in seven cases of the interior of the appendix, where the contents were to be considered as normal or not affected with the inflammatory process in the neighborhood, showed no bacteria in two cases. This result is surprising in view of the enormous number of bacteria always present in the large intestine. Of three cases of peritonitis diffusa, secondary to appendicitis or peri-appendicitis, the bacillus coli communis was found in two, the bacillus pyocyaneus in one, and one case was sterile. In this group of peritonitis diffusa are also three cases which had their origin in the gall bladder, one being secondary to a choledochotomy. In two of the cases the bacillus coli communis was found, and in the third the staphyloccus albus. In this connection it may be mentioned that of three cases of gall-stones the bile contained staphylococcus albus in one case, bacillus coli communis in one case, and the remaining case was sterile. Of six cases of peritonitis from various causes, in two bacillus coli communis, in two streptococcus, in one bacillus pyocyaneus were observed. In a single case no bacteria were present. Four cases of intestinal obstruction formed another group of cases, in three of which there was a fibrinous exudation in the peritoneum. Of the four cases but one yielded an organism of any significance, namely, the staphylococcus albus. Two were apparently sterile. The last group of cases are those in which the fluid of hernial sacs was examined for bacteria. Of seventeen cases all were sterile except two, and these positive cases were from four of beginning or advanced gangrenes of the gut. The absence of bacteria in the other two cases of gangrene, where the conditions for their migration through the wall of the gut were apparently favorable, is surprising. On the other hand, in the sac fluid of two out of three epiploic herniæ, where bacteria from the intestine were scarcely to be expected, bacteria could be demonstrated. In two hernial hydroceles the fluid was sterile. The results are of interest as showing that we are as yet ignorant of all the causes which determine the migration of bacteria through the intestinal wall. It is also interesting to note that the examination of the contents of a hernial loop of the small intestine, accidentally opened at operation, showed few bacteria. This is another proof of the relatively small number of organisms in the small intestine as compared with those in the larger gut.

In addition to the foregoing cases the authors have included in their list of examinations a number of other cases more or less germane to the subject of peritonitis, but which have no special interest. Among these, however, should be mentioned a case of sub-peritoneal abscess and a case designated as empyema of a hernial sac, in both of which tuberculosis originating in the vertebræ has not been sufficiently excluded. The latter case especially serves to emphasize how desirable it is, for the bacteriologist who works with pathological processes, to have some knowledge of pathology. The technique employed in the work is, on the whole, satisfactory. The study of the biology of the different bacteria is perhaps, in general, as thorough as is necessary. A feature of their investigation which is of special interest from a bacteriological point of view is the study of thirty representatives of the bacillus coli communis, with reference to their various cultural peculiarities, number of locomotor organs, and other characteristics. The results would seem to show that scarcely any two of them are exactly alike. The differences, however, in many cases, are only such as one would encounter in studying parallel cultures of almost any organism, and we do not think that the writers are justified in considering many of such differences as constant. It is well known that different varieties of the bacterium coli exist, but the division of these thirty representatives of that group into as many as twenty varieties does not seem warranted from the observations. Of the thirty, two at least are clearly not to be classed within this group of the bacterium coli, as would appear from a consideration of their cultural peculiarities as given by the writers. In several cases bacilli somewhat resembling the Klebs-Löffler organism have been observed. To these, however, no pathogenic significance is ascribed. We cannot agree with the writers that this

is probably the pseudo diphtheria bacillus of Löffler. The cultural peculiarities of that organism are too little known for it to be identified, and our own experience has seemed to show that there may be nearly as many pseudo diphtheria bacilli as there are observers. In addition to the results of their own experimental work, the speculative and historical aspects of various questions connected with the subject of peritonitis have been well considered by these investigators. As to prognosis, they state that no conclusion can be drawn from the species of bacteria present. In those cases, however, where no bacteria are to be demonstrated, it would seem that the result is, in general, more favorable than in those where bacterial forms are present.—*The Boston Medical and Surgical Journal.*

Trichinosis.—Dr. P. Cerfontaine has recently made a study of trichinosis during an epidemic of this disease in Belgium. His researches showed that during the first two periods the cysts are destroyed in the stomach, in which the larval trichinæ either live for some time or they pass at once to the small intestines. Here they grow, and fecundation is effected on and after the second day of infection; the males of a slag of varying length in the intestine are expelled with the fæces. In the female the development of larvæ commences immediately after fecundation. The embryos begin to be set free about the sixth day of infection. Dr. Cerfontaine then states a fact which we believe to be new, that a certain number of the females penetrate into the wall of the intestines, and even into the mesentery; these have more chance of infecting the organism than those which remain in the intestinal canal, since their embyros cannot be expelled with the fæces. It is probably by means of the lymphatic systems that the parasites first make their way into the tissues of their host. We have not before noticed any observations showing that adult trichinæ penetrate the tissues of their host, and if confirmed, will explain some phenomena relating to trichinæ for which we have hitherto found no explanation. It certainly explains the violence of the gastro-intestinal troubles which often characterize the beginning of the malady.

In continuation of this subject, we notice also that Dr. J. Sawtschenko has made a study of the propagation of disease by flies, and found that when fed on cholera corpses that the cholera bacteria were found in their excrement and that they lost none of their virulence during the transit through the fly's intestines. The doctor concluded from these experiments that flies not only serve to spread disease infection directly, but that each patch of excrement must be reckoned as a further centre for the extension of disease.

Winter Climate of Rome and Florence.—According to the *Lancet*, Rome, which was a favorite winter resort for *poitrinaires* in the times of our grandfathers, has lost its reputation in this particular, and with justice. Its climate has neither the mildness nor the equability which the pulmonary patient usually craves. In the winter months the *tramontana* often sweeps down from the spurs of the Apennines with destructive bitterness. The streets —at least those of the mediæval city, now largely disappearing before the relentless march of modern "improvements"—do not well admit the sun's rays, and the alternations from sun to shade temperature are sudden and extreme. Nevertheless, as compared with northern lands, the climate has much charm, and can be safely recommended to many patients, excluding those who are the subjects of grave pulmonary disease. The same remarks apply with even greater force to Florence. The mountains are there nearer the city, and the *tramontana* blows with greater severity. Again, Rome, which is distant only about fourteen miles from the sea in a straight line, possesses a climate that is partly marine, whereas Florence, distant about fifty miles from the sea, has a distinctly continental climate. Neither of these cities, unparalleled as are their claims from the æsthetic, literary, and antiquarian point of view, possesses the requisites for a really good winter or spring resort. They yield their maximum of attraction and advantage not to the serious invalid, but to the jaded and overworked individual to whom variety of interest is more important than ideal meteorological conditions. Further south, on the Bay of Naples, at Sorrento, Castellamare, or Capri, spring comes early, and winter often departs with the month of February. On the other hand, the traveller in Lombardy must be prepared for severe cold prolonging itself well into the spring.

The Microbes of Scorbutic Gingivitis.—Dr. Babès's latest experiments in this direction were made in three typical cases of scorbutus. Small portions of tissue from the gums, also specimens of blood, were submitted to microscopical and histological examination. (*New York Medical Journal*). There was a diminution of the red globules, with marked leucocytosis. The microscope revealed a characteristic bacillus, elongated, thin, undulating, and forming thick masses. In the tissue the same colonies existed to such an extent as almost to form a false membrane. In connection with the peculiar bacillus numerous other bacteria were present, particularly a streptococcus. Inoculations of animals with the culture substance produced death with typical lesions of scorbutus. Autopsies and microscopical examinations disclosed the characteristic bacillus in great numbers in certain localities, such as the lungs and their capillaries, the tissue of the gums, and the viscera. They were not found in the hæmorrhagic effusions. The cultivation of the bacteria presented great difficulties on account of the presence of the streptococcus. It was found that an injection of the cultivation of streptococcus alone did not produce the typical disease, but with the suspected material from the scorbutic gingivitis death resulted from hæmorrhagic disease. Babès has not yet finished his experiments, but he is under the impression that the bacillus is one peculiar to the buccal region, and that in consequence of a depression in the general health these bacteria take on active changes producing the typical lesions. Again, it might be possible that the gingivitis was due to the presence of the streptococcus, and the general scorbutic symptoms to an invasion of the suspected bacillus through the mucous membrane.

Hotel Hygiene.—At a recent meeting of the Société Normande d'Hygiène Pratique, M. Percepied read a paper on the transmission of infectious diseases in hotels, where the bedrooms are occupied in turn by invalids and healthy persons. (*New York Medical Journal.*) It is principally in reference to the watering-places or the winter resorts that the attention of physicians and of the public has been aroused, he says, and in a number of resorts the suggestions mentioned in his paper have been adopted and have given rise to reforms, still in their infancy, but destined to extend rapidly. It is a great mistake, in his opinion, to limit hygienic precautions to health resorts only; all hotels, whatever they may be, should have the same rigorous care. The condition of health of the people received at these hotels is not known, and, granting that acute infectious diseases are relatively rare, it is certain that invalids with chronic diseases, such as tuberculosis, are frequent patrons, and the fact that the majority of the travellers remain only a short time cannot be brought forward as an argument. They have the right to remain as long as they please, and they also have the right to demand that all sanitary precautions shall have been taken in the rooms that they occupy. The subject under discussion applies only to travellers, although there is much to be said with regard to hotel kitchens and lavatories, and, above all, to the condition of health of the cooks and the other employees who live there. M. Percepied confined himself to saying that kitchens should be provided with draught flues, and be sufficiently well ventilated for the odors not to pervade the hotel. Infectious diseases are due to germs that are very unyielding and retain their virulence for a long time, and these germs may be in every part of a

room that has been occupied by an invalid; in the bedding, as well as on the walls or on the floor. Knowledge of these facts imposes the necessity of modifications in order to render the rooms habitable and free from danger to those occupying them. First of all the room should afford air in proportion to the number of persons occupying it, and should be well ventilated and sunny, for the importance of sunlight and air as hygienic factors is well known. The walls should be hard-finished or coated with an impermeable paint which can be washed, and, so far as possible, all corners should be rounded to make them accessible to washing. Mouldings, unless rounded, should be discarded. Carpets should be rigorously prohibited, and a parquet floor which can be washed, substituted, or a covering of linoleum of an artistic and pleasing design used. An advantage to be gained by this is the abolishing of the spaces which always exist between the boards of an ordinary wooden floor. If the traveller desires to be more comfortable, he can have a movable carpet or rug, on condition that after his departure it is beaten and passed through a disinfecting bath before it is used again. The same precautions should be taken with regard to carpets. In rooms that are not very much used a heavy linen covering can be substituted for carpets, which can be sent to the wash like clothing. For the same reason curtains should not be tolerated, except those that can be washed. White ones are preferred, as the monotony can be relieved with a border of embroidery in bright colors. Heavy materials, like plush and velvet, should never be used. The furniture should be very simple in design, so that it can be cleaned easily. Wooden furniture, wardrobes, bureaus, and toilet-tables should be varnished or waxed, or, if preferred, lacquered. Chairs should have caned bottoms. Thus it is possible to conform strictly to hygienic laws, and at the same time preserve an artistic appearance. Everywhere, where it is possible, brass or iron bedsteads should replace those of wood. Toilet articles, especially the glasses, should be washed every day with the greatest care. After the departure of a patron they should be washed in an antiseptic solution, such as a half per cent. solution of corrosive sublimate, and the bedding, towels, etc., boiled in alkalinized water. With regard to the means of lighting hotels, electricity is to be preferred, although that is a question of secondary importance. The heating should be with wood, coal, or coke. After a room has been occupied by an invalid, all the bedding and other linen should be sent to the disinfecting bath, and the walls, boards, and furniture submitted to antiseptic washing and antiseptic spraying. These precautions should not only apply to the bedrooms, but extend to the different rooms that the patrons have used, although with less strictness. The curtains of the parlors, where they remain but a short time, do not require such rigorous treatment. Nevertheless, draperies should be avoided and carpets prohibited. The same precautions should be observed in the dining-room. Here particular care should be given to the washing of the glasses, the forks, and the spoons. The former, after each meal, should be washed in an antiseptic liquid, and afterward well rinsed in clean water, and the latter in boiling water. The vestibules, halls, and stairways should be without carpets and should be wiped every morning with a cloth wet with an antiseptic liquid. The closets should be large and well ventilated, and have proper appliances for flushing. These precautions should extend to the rooms of the employees, where the sanitary conditions should be under the strictest surveillance. As soon as a case of sickness is discovered isolation should be practised in order to take the necessary precautions as regards disinfection. These are the measures, the author says, which should be resorted to at the present time, and failure to do so shows a culpable indifference. At first it may seem that these precautions would be a source of expense to the hotel-keepers, but the abolishing of curtains, carpets, and furniture covered with rich silks and velvets will prove economical for them in the end, and, if they are properly carried out, any danger of infection will nearly always be averted.

Treatment of Morphinomania.—Dr. Berillon, of Paris, read a paper before the Neurological Section of the Rome Congress on the treatment of the morphine habit by hypnotic suggestion. The author was not a partisan of rapid suppression, which he thought was exceedingly dangerous to the patient. Yet gradual suppression, he said, is not without its inconveniences. As a patient, upon whom he was trying this last named method, once said, "This is like cutting off a dog's tail an inch at a time." This is not true when hypnotism is employed, for then the inch is cut off each day without pain or inconvenience of any kind. The period of convalescence is very short, and there is no fear of relapse. The author concluded that gradual reduction, each time effected under the influence of hypnotic suggestion, is the only rational and safe method of cure of the morphine habit. Dr. Berillon is the editor of the *Revue de l'Hypnotisme*, of Paris. Dr. Tanzi, of Palermo, said that he had obtained a complete cure by this method, but other men who discussed the paper had not had such good results, their patients having relapsed into the habit after the hypnotic séances had been discontinued.

The Mammillary Body in Man.—Dr. De Sanctis, of Rome, presented a communication at the recent Congress of which the following were the conclusions: 1. The corpus mammillare of man is developed from two ganglia, the median and the lateral. The lateral ganglia has no connection with the *pedunculus corporis mammillaris* (fascia tegmentalis of Meynert), but is in relation with the *columna fornicis*, which arises in great part from it, and, to a lesser degree, from the median ganglia. 2. The median ganglia of the corpus mammillare is in relation with the complexus of the fascia of Vicq d'Azyr and of the fascia tegmentalis of Gudden. 3. The medullary capsule (Gudden) of the corpus mammillare is in relation, by its *ventral* portion exclusively, with the columna fornicis, and by the median portion in great part with the fascia of Vicq d'Azyr—fascia tegmentalis—in less part with the columna. 4. The rete endomammillare is formed almost wholly from the columna, while the two ganglia are given off from the fascia of Vicq d'Azyr. 5. The fascia of Mahaim has no relation with the fasciæ of the columna fornicis.

Surgical Operations and the Daily Papers.—Not long ago an operation was performed on a young girl suffering from exophthalmic goître in the Salpêtrière Hospital, at Paris. The patient died, and a few days later an evening paper appeared with the sensational heading, "Un Meurtre Médical." The writer made out that the surgeon incriminated had been actuated by vivisectional sentiments in performing an unnecessary and cruel operation on the poor unwilling victim. The said scribbler had evinced his ignorance of the hospital of which this barbarous proceeding had been the scene, and he had even applied at the wrong establishment for information. The cry was, however, taken up by other journals, and "*l'incident de la Salpêtrière*" became town talk. From a letter addressed by Dr. Brissaud to Professor Brouardel, Dean of the Faculty—a letter in which the dean is asked to lay the case before the Director of the Assistance Publique—it transpires that Professor Poucet, of Lyons, the inventor of the operation, was the operator. Dr. Brissaud had in his wards two young women with exophthalmic goître, unamenable to ordinary medical treatment. One was, at her own request, operated on with complete success. The other, the deceased, was a minor, and the consent both of herself and of her parents was obtained before operative measures were taken. The affair came in due course before the Municipal Council, and a resolution was carried urging the authorities to exercise more vigilance, and discouraging operations in Paris hospitals by provincial surgeons.

MANAGEMENT OF THE BREASTS AND NIPPLES BEFORE AND DURING THE PUERPERAL PERIOD.

By ERVIN A. TUCKER, M.D.,

NEW YORK.

RESIDENT PHYSICIAN, SLOANE MATERNITY HOSPITAL. INSTRUCTOR IN PRACTICAL OBSTETRICS, COLLEGE OF PHYSICIANS AND SURGEONS.

If I had had the wording of the subject allotted to me by our secretary, I would have put the word "nipples" in the place of emphasis, before "breasts," for it is my experience that, if the nipples are taken care of, the breasts will take care of themselves. The subject is trite, and yet, if the physician has no prompt radical remedy for sore nipples and breasts at his disposal, these troubles, small at first, may soon become serious. Every physician soon settles down upon some plan of treatment which he of course thinks is the best, but many of these plans are far from satisfactory, if I am to judge from remarks that I have heard. Almost every treatment that the mind can conceive has been tried at some time or other, and yet pain and discomfort for mother and child and worry for the physician seem to be as frequent as ever. The plan of treatment I shall offer you is not new, except in its arrangement of detail, and my only excuse in presenting it that this line of treatment has proved itself successful in an experience limited to a few thousand patients. Most of the cases I have seen had made during pregnancy no preparation for lactation, and yet the number of nipple and breast troubles has been amazingly small. After such an experience you cannot expect me to have much faith in the efficacy of remedies said by many authorities to be essential in preparing these organs for their functions.

The only breast troubles liable to occur during pregnancy are a feeling of heaviness at times, which can easily be relieved by a firm binder or a properly fitting corset, and the slight aches and pain which may shoot through these developing organs. Gentle massage of the breast best relieves these pains.

I was taught, as no doubt most of you have been, that the use of astringents is beneficial in preparing the nipples for later use, but I have abandoned, with benefit, I think, this practice of using astringents during pregnancy. I would limit manipulation of the nipple to those cases in which it is imperfectly developed—the slightly inverted, or flat, or protruding with a depression on top ("crater-nipples")—in such cases patiently practised manipulation will do much to perfect the nipple. If true inversion of the nipple exists, the woman is debarred from nursing. For a perfect nipple the only treatment necessary during pregnancy is cleanliness, and this cannot be insisted upon too strongly. If there is reason to believe that the patient will not pay proper attention to cleanliness, then direct her in plain language to wash the nipples daily with soap and water. I saw a case about two years ago in which the nipples were said to have fallen off—a most remarkable event—but investigation proved that a crust, composed of dirt and dried secretion, had fallen from small nipples. I mention this case simply to illustrate to what an extent dirt may accumulate upon this organ, if it is neglected.

During lactation the proper treatment of sound nipples and breasts, in order to keep them sound, includes care of the child's mouth—it must be clean before as well as after nursing; it includes a clean nipple for the child's clean mouth to nurse from; and it includes regularity in nursing. My routine method is to have the child's mouth washed out, just before nursing, with a saturated solution of boric acid, and the nipple, with surrounding part of breast, is washed with the same solution. After nursing twenty minutes the child is removed and its mouth again washed with boric acid to prevent sprue; the nipple is also washed with boric acid, dried with clean lint, then a clean dry powder applied (*e.g.*, subnitrate of bismuth and salicylic acid, equal parts by volume), a little square of clean dry lint is placed upon the nipple, then the breast-binder or nursing corset put back in place. The child should never be allowed to macerate the nipple by holding it in the mouth when not nursing. Nothing will make a nipple sore so quickly as maceration in the child's mouth or in the milk from a "weeping breast." The nipple must be kept dry all the time except during the twenty minutes' nursing.

A custom, which I would especially recommend to you, is not to allow the child to nurse at night from the time the mother retires (say 10 or 11 P.M.) till she rises (say 7 or 8 A.M.) To those who have been in the habit of allowing the child to nurse at intervals of three or four hours during the night this may seem to be a scheme to starve the child for the sake of the mother's comfort, but, I assure you the child will not starve, on the contrary, it will thrive, provided of course it is healthy. To sickly or premature children this rule does not apply. If this plan is pursued from birth to weaning, it is pleasant to know what a calm settles down upon the household at night—the child will sleep just as long as the mother does and will have an appetite for breakfast that would shock a night-nursing child, while the mother (not to mention the father) will be so refreshed by the uninterrupted sleep that she will be in better health and better able to supply good milk.

When this ideal state of sound nipples and breasts does not exist, we must try to discover the cause of the trouble. Sometimes the nipples are simply tender—a little silver nitrate, eight per cent., or alcohol, fifty per cent., applied after nursing will soon cure ordinary cases. If the nipple is exquisitely tender, cocaine applied just before nursing will relieve until the nipple becomes tougher. Care must be taken to remove the excess of cocaine, or the child will refuse to nurse. Nipples quickly toughen during the process of nursing and often require no treatment. So many nipples never become sore at all that I do not consider a preparation during pregnancy necessary. Cleanliness is the only prophylaxis that I would advise.

In worse cases the nipple skin cracks on top or at the base or both. The cracks at the base heal more slowly, but the following treatment will cure even these deep cracks at the base almost as well as it will the superficial cracks and erosions. After each nursing apply a drop of eight per cent. silver nitrate solution to the raw surface, then dry and powder the nipple as usual. The theory upon which this treatment is based is that the nitrate, by coagulation of the raw surface, forms an artificial pellicle or scab under which the wound heals. I know of nothing that acts as well as the nitrate does for this purpose. To make it effective the nitrate must be applied after every nursing, until a scab thick and strong enough is

formed to withstand the child's suction. To protect this scab from being pulled off at every nursing, a nipple-shield must be used. After repeated trials of many kinds of shields I have come to consider this the best (modified Barclay shield). Applications of the nitrate for one or perhaps two days will suffice, provided the nitrate is applied directly to the raw surface from the start. A frequent cause of failure to make this method work is that the nitrate is simply dropped upon the nipple and does not touch the raw surface. If the application is too painful, as it may be in some sensitive women, a little cocaine may be used. To sum up—the whole treatment is to apply silver nitrate for one or two days, and to use a shield until the nipple is sound. By this plan the child never loses a meal, the breasts do not cake while the nipple is healing, and the chances of infection of the breast through the denuded nipple are reduced to a minimum.

Caked breasts must often be treated. When milk is secreted faster than it is withdrawn and this secretion takes place unevenly, the breast becomes tense or lumpy —a condition which is painful just in proportion to the unequal distention existing between different parts of the breast. If the whole breast is uniformly distended with milk, the caking may be quite or nearly painless, but if one part of the breast is hard and other soft, the hard parts are more or less painful. If the woman is nursing, massage is the only treatment. Ten or fifteen minutes spent in gently stroking the breast from periphery toward the nipple, which is the only way that mammary massage ought to be done, will relieve the pain, no matter how badly the breast is caked, without expressing a drop of milk. Extracting milk from the breast by a pump or the hand or the child's mouth will also produce some relief, but it is not as effective as massage. In a hospital extra nursing by two or more children does very well, but in private practice massage is preferable. The relief gained by massage will last several hours. The temporary caking, which often appears three or four days after delivery, can always be relieved by nursing and massage. But if the woman is for any reason not to nurse or has to stop nursing, a free catharsis, caused by mild salines, and the use of a tight breast-binder, with massage three or four times a day, will relieve the worst possible case of caking.

Should mastitis occur at any time, whether complicated by caking or not, we have a much more serious condition to combat; but, if the proper treatment is begun when the initial chill and fever and pain in breast occur, every case can be cured. My opinion is that mastitis, whether mild or severe, partial or general, is always caused by infection through the nipple. The treatment of sore nipples is therefore really a prophylactic treatment of mastitis and should always be so regarded, then a sore nipple will not be considered a trifle, but will be treated promptly and thoroughly. The best treatment for mastitis, and this aborts a threatening mammary abscess at the same time, is drainage and cold. Drainage of the breast is obtained in two ways—nursing from the affected breast and free catharsis caused by liberal exhibition of salines. The breast can be kept well drained, if you use these two measures thoroughly. All the time that the child is not nursing cold can be applied by means of an ice bag or coil. Massage I avoid in mastitis cases, if possible, relying upon the drainage and cold. Whether you cure these cases or not will depend upon when the treatment is begun. If you begin treatment late, or do not treat them at all, many cases will end in abscess. The method just described is so simple and has given such satisfactory results that I would recommend it to the exclusion of all other methods.

When the abscess is inevitable, heat should be applied to the breast. Hot poultices often renewed will give great comfort till it is time for incision.

To dry up the milk the only essential is to stop nursing. A tight breast-binder may be applied for the sake of comfort. These simple measures suffice in most cases, but catharsis and massage for the caking may be necessary if the breast was in full activity when nursing ceased. Twenty-four hours of discomfort must be expected in every case, beginning about a day after nursing stops. The use of belladonna, etc., I consider superfluous. The milk will dry up, no matter what you do, if the child ceases to nurse.

In applying a tight breast-binder the nurse should see that the breasts are brought well up together in front and that firm pressure is so applied that no parts of the breast are left uncompressed. A little cotton, properly packed in, often aids in securing even pressure. The comfort given to the patient by a properly applied breast-binder can hardly be over estimated. If not properly applied, it may become a source of great discomfort because of unequal distribution of the pressure.

In this short paper I have tried to give what I think are the essentials of the subject under discussion. I have purposely refrained from mentioning any methods which have not stood a good test in actual practice. I will only add that I hope you will find them as satisfactory as they have been to me.

Sloane Maternity Hospital, May 10, 1894.

INTESTINAL APPROXIMATION: ITS PATHOLOGICAL HISTOLOGY OF REUNION, AND STATISTICAL ANALYSIS.[1]

By J. B. MURPHY, M.D.,

PROFESSOR OF SURGERY AND CLINICAL SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO; PROFESSOR OF SURGERY, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO, AND PRESIDENT OF, THE MEDICAL STAFF OF COOK COUNTY HOSPITAL; ATTENDING SURGEON TO ALEXANDER BROTHERS' HOSPITAL; CONSULTING SURGEON TO HOSPITAL FOR CRIPPLED CHILDREN; FELLOW OF ACADEMY OF MEDICINE, CHICAGO, ETC.

Mr. President, Fellows of the Academy: In accepting the invitation of your worthy Chairman, Dr. Bryant, to read a paper before this great scientific body, I appreciated the honor conferred upon me, and realized the fact that in this audience would be gathered many men who had spent the better days of their professional life laboring in this special field, and whose achievements are an ornament to surgery, a heritage to the profession, and of incalculable value to humanity.

I am greatly relieved by the knowledge that I will be assisted in the presentation of the various aspects of the subject by the gentlemen who are to participate in the discussion. If some phases of the subject of intestinal approximation appear to be treated cursorily, it is because the gentlemen who follow have had a greater experience in certain procedures, and are therefore better able to present the subject from a practical stand-point. I realize that I have no novel propositions to make, nor have I a new device or method to present for your consideration. It is my desire to discuss the pathological histology of reunion, and to give an impartial retrospection of the clinical achievements by the different methods under the same favorable circumstances. Therefore I will not enter into antiquities, nor even into the mediæval history of intestinal anastomosis, but will confine myself to the records of the last five years. The reason for this is apparent, as no method of approximation, however perfect in the pre-antiseptic period, could give the favorable results which are attainable at the present day. With a slight reservation, the same may be said of the methods in the antiseptic epoch. In the first period I include all before the advent of Listerism, in the second, the methods employed from 1872 to 1888. In this period the knowledge of physiology and histology upon which the technique of intestinal surgery was based, as well as the technique itself, were imperfect, which was very detrimental to the success of operative procedures. In the third epoch, from 1888 to the present time, all methods have had equal opportunities to produce the same results, as the principles governing intestinal anastomosis have been well established.

[1] Read by special invitation before the New York Academy of Medicine, December 7, 1893.

In order to attain good results in intestinal approximation we must consider the means of: 1. Securing accurate contact of surfaces. 2. Producing speedy and permanent adhesion of the approximated portions. 3. Maintaining an opening sufficiently large for immediate purposes. 4. Producing a cicatrix that will not contract to a deleterious degree. 5. Accomplishing all of these in the most simple and rapid manner.

The means that have been employed to attain these ends are well classified as follows: 1. Suture. 2. Suture with mechanical aid. 3. Mechanical means.

Before considering the special application of the various methods, let us devote a few minutes to the anatomy of the organs to be approximated. For purposes of approximation, the points which concern the surgeon most are: 1. The strength of the wall of the viscus. 2. Its histological power of agglutination and regeneration.

I have determined experimentally the strength of the walls of the various hollow viscera of the digestive tract against diastaltic pressure, with the following results: The wall of the stomach in large, living, adult dogs withstood an average pressure of 8 pounds before the peritoneum ruptured; it required 9 pounds to rupture the entire wall of stomach. The peritoneal coat of duodenum gave way opposite mesentery under a pressure of 10 pounds. The lower portion of ileum withstood a pressure of 8 pounds, when it ruptured on the convex side: the peritoneal and muscular coats gave way under 6½ pounds. The ileum, two yards above the ileo cæcal valve, ruptured under 7 pounds. In the middle portion of the jejunum the peritoneal coat ruptured at 7 pounds, and the entire wall at 11 pounds on the convex side. The lower four inches of ileum, cæcum, and four inches of colon ruptured at 7½ pounds for the peritoneal coat, and at 8½ pounds for complete rupture. The rupture invariably occurred on the convex side of the ileum, one-half to three-fourths inch from the attachment to the colon. The colon ruptured at 15 pounds, the muscular, serous, and mucous coats giving way before the tunica propria.

With tube inserted in the papilla of the ductus communis choledochus, the pancreatic duct withstood 11 pounds pressure before rupture. The gall-bladder and cystic duct resisted a pressure of 13 pounds before the gall-bladder ruptured.

In only one of the experiments on the alimentary canal, including the gall-bladder, did air escape into the mesentery, showing that the walls of these hollow viscera in the dog possess a greater resistance at the seat of the mesenteric attachment, where there is no peritoneum, than in the portion covered by peritoneum. It was noted that under 3 to 4½ pounds pressure, small bubbles of air could be seen passing through the mesenteric veins. The order of rupture of the coats was: 1, peritoneal and muscular coats, in an irregular line, in the long axis of the bowel: 2, mucous coat, which was torn in shreds, parallel to the axis of the bowel; and finally the tunica propria, which always ruptured parallel to the long axis of the bowel. When the mucous and submucous coats were divided before the distention, the other coats ruptured under 1½ pound pressure.

The following were the average results obtained on cadavers four days after death: Peritoneal and muscular coats of stomach lacerated extensively under 3½ pounds pressure, and ruptured always on the anterior surface of the lesser curvature close to the mesenteric attachment, under 4¾ pounds pressure. Jejunum ruptured under a pressure of 4½ pounds, always on the mesenteric side, the peritoneal and muscular coats on the convex side giving way before complete rupture. The colon, to within four inches of the ileo-cæcal valve, ruptured under 4½ pounds pressure. The lower four inches of ileum, cæcum, and eight inches of ascending colon included in the same ligatures, ruptured under a pressure of 7½ pounds, the rupture occurring on the mesenteric side of the colon. The peritoneal coat of the sigmoid flexure ruptured under a pressure of 2¾ pounds, and the tunica propria under a pressure of 4¾ pounds. With the tube inserted in the papilla of the ductus communis choledochus, rupture of the pancreatic duct occurred under a pressure of 5¾ pounds; with the tube inserted in the cystic duct, the gall-bladder ruptured on the peritoneal side under a pressure of 12 to 22 pounds.

These experiments show that the resistance of the wall of the gastro-intestinal tract against diastaltic pressure is sustained, (1) by the mucous, muscular, and serous coverings, and (2) after a rupture of these by the submucous coat (tunica propria). The mucous membrane offered but very little support to the wall of the bowel, as it tore into parallel shreds over the entire circumference during the process of distention.

To maintain the strength of the bowel it is necessary to have the submucous and serous coats of the wall united at the seat of approximation. The tunica propria is used as a mechanical support, but its regenerative power is slow and very limited, while the peritoneal coat has great and rapid power of adhesion and proliferation. Therefore the serous coat is the one upon which the surgeon must depend most for primary agglutination and adhesion, on account of these two properties of the peritoneum, and it must always receive the greatest attention in all methods for producing intestinal anastomosis. It has been repeatedly observed that moderately firm adhesions between two approximated, abraded, or injured peritoneal surfaces, form in six hours when the surfaces are aseptic. After isolation of the layers, the mucous membrane, muscular layer, and serous coat tear in all directions with equal and moderate force; the submucosa cannot be torn transversely, but with great force it ruptures. It can be torn longitudinally with considerably less pressure. As we must depend upon the submucosa for retention of the coaptation, the Lembert suture should therefore be inserted, when we desire to give the union its greatest strength, transverse to the longitudinal axis of the bowel, and should embrace the submucosa, as by Cushing's right-angle suture. If the surfaces are septic, union will not take place, but should they temporarily adhere, the exudate will rapidly disintegrate and the surfaces separate. Sepsis is therefore a factor of great moment in securing permanent union after intestinal approximation. No matter what means are employed to produce the approximation, the surfaces will not unite if they are septic, for the same reason that we have an absence of primary union in septic incised wounds in other parts of the body.

In reporting autopsies following non-union in intestinal approximations, it is important to state whether a septic peritonitis existed at the time of operation.

Histology.—From the articles on the pathological histology of the union of the bowel with the Czerny-Lembert suture, by Ritschl and Walter Rindfleisch, we take the following: It is important to know from many standpoints how the reunion of a divided intestine takes place, how rapid the adhesion, how soon definitive union occurs, and what disposition is made of the suture material. Up to the present time the greatest attention has been paid to the pathology of perforations, the causes of death following, and the new methods of approximation, and little attention has been given to the pathology of the reparative process itself.

An examination of an end-to-end approximation of the intestine (Czerny-Lembert suture), forty-eight hours after the operation, shows the mucous membrane very much contracted and an exposed free submucosa. This submucosa is covered with lymph and pus corpuscles: the seat of approximation is recognized by a striated, infiltrated tissue. The muscular coat has undergone no perceptible change. The serosa and omentum are notably thickened and congested. The stitch holes can be observed, the surrounding tissue is densely infiltrated, and an intensely dark ring around the stitch canal. Coils of intestine are adherent to each other at site of suture, and bent at short curves.

Fourth Day.—Firm adhesion: suture does not appear on surface; around many of the sutures stitch abscesses

have formed. Knuckles of intestine firmly adherent to wall at seat of suture, bent at sharp curves, but still admit the passage of water.

Microscopically the union of the ends is not produced by a juxtaposition of separated coats of the incised surfaces, but the connection is made by a zone of inflammatory infiltration with a substratum of the remains of the serosa and muscularis. The mucous membrane has healed over the formerly exposed submucosa, its base protrudes and rests upon the cicatricial tissue, so that many of its glands are deposited thereon. In the mucous membrane, especially in the tunica propria, there exists, for three or four centimetres, a catarrhal condition not infrequently accompanied by wandering leucocytes above and below the union. The submucosa is almost approximated from either side, and but very little changed from its normal condition. A very slight cell-proliferation and enlargement of the vessels exists, so small that it can scarcely be distinguished from its normal condition. The muscular coat shows a marked cell proliferation and vascularization, and takes part in the formation of the scar. The border of the serosa is obliterated in its union with the omentum, and is thickened at the seat of the suture from five to ten times its normal size. One stitch abscess is formed where the stitch drew in a portion of the mucous membrane.

Eighth day —At the seat of suture coils of intestine are adherent to the sutured surface and also to each other, forming a bunch. The descending portions of the intestine are grouped around the site of the suture in short curves. The adhesions are broad and firm; they cannot be torn, but must be cut with scissors. Notwithstanding the short curves, there is no angle produced sufficient to obstruct, the lumen being free throughout.

The approximation projects above the level of the surface of the mucous membrane, and there is an ectropion of the mucosa from the scar.

Microscopical Examination.—At the muscularis the tissue is retracted; there is a disarrangement of the direction of the fibres, with a small multiplication and infiltration of cells recognizable. The serous surfaces are united to each other and to the omentum without much change of their structure, although there is a thickening of the zone by inflammatory exudate.

Twenty-first Day —Omentum adherent over one-third of line of suture: the bowel contracted at the seat of suture to the size of a dime, while above and below the intestinal lumina were of equal size, or about the size of a nickel. On the mucous side is found a small furrow with sharp edges, showing the seat of cicatrization. There is a small light-gray scar on the furrow.

Microscopical Examination.—The mucous membrane is united without interruption. The muscularis mucosa is separated by a distance of from 1 to 2 mm. The greatest irregularity prevails in the union of the muscularis, the muscular fibres being distributed in all directions. The serosa is somewhat thickened. The silk can be seen unchanged, and surrounding it is a cell infiltration. The tunica propria does not differ in the least from its normal condition. There is a spindle-shaped termination of the muscular coat in the scar. The new formation of muscle cells is inconsiderable.

Eighty-sixth Day.—Omentum adherent at site of suture. Intestines adherent in very short curves, but no angle produced. No obstruction. There exists a circular contraction; the lumen at the seat of suture is about the size of a nickel. This circular contraction is formed by an elevation 2 to 3 mm. in thickness above the surface of the mucous membrane, which is always produced by a Czerny-Lembert suture.

Microscopical Examination.—There is an elevation upon the mucous surface, in the centre of which is a depression where the mucous membrane rests upon the submucosa. The submucosa is unchanged except on its extreme outer limits, where its fasciculi extend into those of the cicatricial tissue. The muscular wall is not perceptibly changed. The serosa in the scar has lost its identity entirely, while on the surface it is united to the omentum, passes continuously over the scar, and has not changed its structure. The suture material is unchanged. It is surrounded by an area of infiltrated tissue of numerous large cells with dark nuclei.

One Hundred and Sixth Day.—Omentum adherent. The calibre at the line of suture, compared with the intestine above and below, is relatively as a dime is to a nickel.

Microscopical Examination.—The mucous membrane shows no evidence of a previous separation. The muscular layers are connected by fibrous bands through the scar-tissue. The muscular tissue up to the line of approximation is absolutely unchanged. The serosa gradually thickens as it approximates the scar, is very vascular, and its tissue becomes more dense, which is caused in particular by an increase in the number of spindle-celled elements. Silk unchanged.

One Hundred and Thirtieth Day —The intestine above and below the scar is of equal calibre.

Microscopical Examination.—The mucous membrane united perfectly, showing no evidence of line of union. The circular muscular fibres held together by a thin band of connective tissue. The longitudinal muscular fibres are much more firmly united, the fibres from one side to the other being continuous.

Conclusions. — From the above description of the pathological conditions, the following deductions may be drawn: The ectropion of the mucous membrane after an incision is passive, and is due to the elastic retraction of the underlying submucosa and muscularis. For this reason, by the Czerny-Lembert suture there is an almost uniform coaptation of the edges of the mucous membrane without the aid of a special suture, which protects by its intimate approximation the underlying tissue from exposure and infection. This would not occur with a Lembert suture alone, as there would be an overlapping or separation without the Czerny. When there is a defect in coaptation of the mucous layer, union must take place by secondary intention, and the tissue is exposed to all of the dangers of infection, viz., non-union, fistula, circumscribed abscess, the same as secondary union upon the cutaneous surface. Glandular tissue is not regenerated over this area.

The submucosa plays an important rôle in intestinal approximation from the moment of coaptation. While it takes but very little part in the regenerative process, we depend principally upon it for support given the suture in retaining the bowel in position. The more transversely the stitch is inserted, the greater its support. Later, a short distance back of the line of suture, there is a pronounced vascularization of the submucosa.

Muscularis.—When an exudate intervenes between the opposing muscular layers, the muscle fibres terminate in spindle shaped processes. When the apposition is perfect, the fibres from the opposing sides unite so accurately that the line of union cannot be discerned.

Serosa.—The serosa plays the most important rôle in the inflammatory or regenerative reaction. By it we have produced the first adhesive exudate, which process commences immediately after approximation, and in a few hours cements the recently united surface, as supported by Jobert's principles. The vascularization and thickening of the serous coat commences and reaches about ½ ctm. in thickness, 3 to 4 ctm. away from the line of union, and becomes more dense as it approaches the line of suture. The omentum that becomes adherent is also greatly thickened by cell-infiltration and increased vascularization, and on the eighth day the adhesions are so firm that they cannot be separated without lacerating the subjacent tissues. Frequently the neighboring coils of intestine become adherent at the line of union; the danger of this is that the loop may be so short as to produce an acute angle in the coil, and thereby cause obstruction. The resistance of the bowel against diastaltic pressure is offered almost entirely by the submucosa and

muscularis; they resume their normal function after a perfect union. From this it will be seen that, in order to procure a perfect result in intestinal approximation a primary union, not necessarily of all the coats but of some, is imperative. It is not necessary that they should adhere to each other, but that the various coats should approximate as closely as possible. In the great majority of cases following suture of the bowel, there are adhesions of coils of the intestines, mesentery, and omentum; as a rule, they do no harm and, I believe, aid in retaining the bowel in the proper direction at the site of union, as well as supporting and protecting the line of suture. *There occurs of necessity, with the Czerny Lembert suture, a degree of stenosis;* this is produced by a protrusion of the Czerny portion of the approximation into the lumen of the bowel through the approximation of the serosa with a Lembert suture. F. Byron Robinson found this produced a complete occlusion of the bowel in three weeks, in the dog.

The following is a report of the pathological changes after operation with button, furnished me by Dr. E. H. Lee. Of specimen four days after operation: Button had been voided twelve hours previous, the shortest time in which a button had liberated itself. Omentum firmly adherent one-half inch above and below the line of union. Thickness of wall of bowel the same at the cicatrix as on either side. Microscopical appearance of transverse section of cicatrix:

1. Serosa, thickened about seven times its normal size by infiltration within, and exudation upon its surface. The line of adhesion between it and omentum cannot be discerned. 2. The longitudinal muscular coat is not united at seat of approximation, though the ends stand in direct opposition to each other. 3. The circular muscular coat is in the same relation and shows granulations. 4. The mucosa is entirely separated over cicatrix; the edges atrophied and overlap underlying layer.

Regeneration of the tissues across the line of union has not yet commenced, except in peritoneum.

Professor Ludwig Hektoen gave the following report:

Longitudinal Section through Line of Union in the Small Intestine of a Dog Thirty Days after End-to-end Approximation with Button: 1. *The Serosa.*—This layer appears but very slightly thickened; it is closely applied to the longitudinal muscular coat over the precise line of union, but beyond this there is some subserous areolar tissue in which are a few small blood-vessels, as well as lymphatics.

2. *The Longitudinal Muscular Coat.*—Quite large parts of this coat are continuous across the union line; but there are masses and bands of cicatricial tissue distributed between these different continuous muscle layers. On each side of the line of union the muscular tissue of this coat appears absolutely normal.

3. *The Circular Muscular Coat.*—This part of the wall is completely interrupted along the line of union by interlacing narrow bands of fibrous tissue that enclose small masses of transversely cut muscle fibres and extend through to the mucous coat. Immediately to one side of this point the circular coat is replaced by a district of loose areolar tissue, containing large blood-vessels with very thick walls and irregular quantities of transversely divided muscle fibre; beyond this district the muscular layer appears normal. To the other side of the union line appears a mass of transversely divided muscle, traversed by bands of fibrous tissue; and then comes an area of loosely meshed tissue, containing very thick blood-vessels, and next the normal muscular layer.

4. *The Submucous Coat.*—As already stated, interlacing bands of fibrous tissue extend through this layer from the muscular coat. On each side of the line of union the submucous coat appears normal, except that on one side the tissue seems rather dense. There are no lymphatic structures in this part of the intestine.

5. *The Mucous Membrane.*—The muscularis mucosæ is completely interrupted, the glands resting upon the cicatricial tissue traced upward from the serosa on a line even with the ends of the muscularis mucosæ, which appears otherwise normal.

The villi are largely absent, not only over the line of union, but elsewhere, and this is most likely due to the rough and extensive handling the specimen has met with since its removal. The mucosa is continuous across the line of union, but much thinner here than elsewhere, and made up of somewhat irregularly arranged glandular tubules lined with short columnar cells; some of these tubules are cut transversely, others longitudinally or obliquely; between the tubules is some small celled infiltration, and projecting from the free surface are irregularly shaped, large and small, villous projections without the usual columnar-celled lining. On each side of the line of union the mucosa appears quite normal, with perhaps a few more small round cells between the tubules than usual.

Recapitulation.—The line of union, which is almost linear in thickness, can be traced by the cicatricial tissue, which, though very small in amount, is distinct. The various layers appear to be in perfect juxtaposition. The longitudinal muscular coat can be said to be almost restored; the transverse muscular, submucous, and the muscularis mucosæ, are almost completely united by connective tissue at the line of union, while the mucosa proper has undergone partial regeneration.

Longitudinal Section through Line of Union in Small Intestine Sixty Days after End-to-end Approximation by Same Means.—In this specimen the restoration of the various layers in the intestinal wall is much farther advanced than in the thirty-days specimen; in some respects the restorative changes are complete. The various layers have been held in complete juxtaposition, and are continuous. There is no thickening of the serous coat, except just across the line of union. The longitudinal and circular muscular layers are continuous and not distinguishable from those in the normal intestine, except for this, that they contain some small spaces (blood-vessels) and occasional traces of fibrous tissue. The greatest change is seen in the submucosa, which has been converted into a thick cicatricial tissue containing vessels with very thick walls. Corresponding to this point of submucous cicatricial thickening, the muscularis mucosæ shows considerable increase in thickness also, due largely to fibrous tissue between the muscle layers, which are now continuous. The mucosa proper over this district does not in any way differ from the mucosa elsewhere, and were it not for the thickening described in the submucosa and the muscularis mucosæ, it would be difficult, if not impossible, to recognize the line of union.

I believe the pathologists have furnished the solution of the slight contraction following this method of union, viz.: 1, The juxtaposition of coats, *i.e.*, apposition of homologous histological elements, with re-establishment of their continuity; 2, the very small amount of connective tissue intervening between the ends of tissue that regenerate slowly, if at all.

In making a comparison of the results obtained by the various methods employed in producing intestinal approximation, there are certain conditions which cannot be accurately estimated, and which must always cause an element of doubt as to the reliability of the deductions drawn from statistics alone. The first of these conditions is the frequency with which unfavorable cases are omitted from the reports, contrasted with favorable ones; second, the condition of the patient at the time of operation, as some surgeons will undertake a serious operation when the patient is moribund, while others will operate only under favorable circumstances; third, the anatomico-pathological conditions for which the operation is performed; fourth, the ease with which a means of producing approximation can be applied increases the frequency of its use, as it is resorted to in desperate cases where more complicated measures would not be attempted, thereby increasing the chances for a greater percentage of unfavorable results; fifth, the dexterity of the operator. A striking example of this is shown in the results obtained

by Riedel in his operation of cholecystostomy in two sittings. He performed this operation 34 times with 34 consecutive recoveries, while in 25 operations of the same kind performed by all other operators there were 6 deaths, a mortality of nearly twenty-five per cent. Another example, is the rapidity with which Abbe can insert thirty-four inches of continuous suturing in his lateral approximation operation, and the good results obtained—5 recoveries in 6 cases. With these facts in view we will proceed with our analysis of the results, beginning with gastro-enterostomy.

Gastro-enterostomy.—The pathological lesions for which this operation is performed are divided into two classes: 1. Neoplasms involving the pylorus or duodenum, producing obstruction; and, 2, cicatricial contractions occluding the pylorus or duodenum. The most common cause of obstruction is carcinoma of the pylorus. In some cases of this disease the obstruction is the first marked symptom of its presence, while in others it does not appear until the disease is very far advanced and the patient greatly emaciated and cachectic. The disease which produces the obstruction in the first class of cases, without excision, necessarily terminates fatally, and the operation of gastro-enterostomy in these cases is only for temporary relief. The patient should not be operated upon unless there is a reasonable chance of considerably prolonging life. While the patients may withstand the immediate effects of the operation, after four or five days they become weaker and weaker, until they finally succumb to the general depression, to which has been added the depressing effect of the operation. The number of cases of this variety operated upon by various methods and the results, are as follows:

Gastro-enterostomy for Malignant Disease.

	Cases.	Recoveries.	Deaths.	Mortality per cent.
Method by suture	28	16	12	42.8
Mechanical means	49	36	13	26.5
Suture with mechanical aid	8	1	7	87.5
Total number operated	85	53	32	37.6
Of these the position was, side to side, in	76	47	29	38.2
End to side	4	3	1	25.0
Unknown	5	4	1	20.0
Of the mechanical means employed, bone plates were used:				
Swedish turnip plates	2	1	1	50.0
Robinson's segmented rubber plate	2	1	1	50.0
Mayo Robson, bone bobbin	2	1	1	50.0
Murphy button	7	6	1	14.3
Suture with mechanical aid. Means employed. Abbe catgut rings	5	0	5	100
Brokaw's segmented rubber rings	2	1	1	50.0
Elastic ligatures	1	0	1	100

Causes of Death by Gastro-enterostomy.

Operation with Suture.

Shock	4	Hemorrhage	2
Exhaustion	13	Complication	2
Peritonitis	4	Unknown	4
Ileus	1		

It has been observed that with all other methods except the button, cicatricial contraction occurred in a greater degree in gastro-enterostomy by lateral approximation than in any other operation. To avoid the stenosis that might possibly occur, I have devised an oblong button for this class of cases, Fig. 1. An opening from two to three inches long can be made with this button, and still its greatest diameter is only 5/8 inch, or the same as the diameter of the small button, and can be passed as readily.

Contraction.—In the post-mortem records we find reports of complete closure of opening from cicatricial contraction in 5 cases. These were all performed by Senn's method with bone plates, that is, of the 28 cases that survived the immediate effects of the operation, 5 of the number on whom autopsies were subsequently made showed a complete closure of the opening. To this must be added, Mr. Larkin's case, in which stenosis occurred requiring a secondary jejunostomy, making 6 closures in all, and representing 20.7 per cent. of the 28 patients recovering from the immediate effects of operation; as many of them have not had autopsies, it is fair to presume that the percentage of stenosis by this method is very much greater than this. Of these 28 cases, the total number in which autopsies were reported is 8; 3 of the patients on whom the autopsies were made died before the end of four weeks, and the opening was patent. In the remaining 5 the opening was closed; the time between operation and death was as follows: 3 weeks, 6 weeks, 4 months, 6 months, and 7½ months; making eighty-three per cent. of stenosis in autopsies where the patients survived three weeks. This would appear to be a very forcible objection to the use of this method in gastro-enterostomy and should exclude its application, except possibly in advanced malignant cases where the disease would terminate fatally before stenosis could ensue.

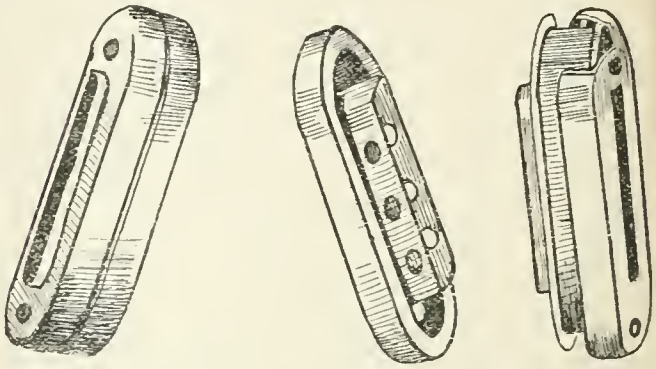

Fig. 1.

The cases of stenosis of pylorus from other causes than malignant diseases are of rare occurrence, and are the ones in which it is important to have an approximation made where the element of contraction will not be of moment for an indefinite period of time. Number of this class:

	Cases.	Recoveries.	Deaths.	Mortality per cent.
Suture	22	18	4	18.2
Mechanical means	11	10	1	9.09
Total	37	32	5	13.5
Of these there were bone plates	10	10	0	0
Swedish turnip	1	0	1	100
Suture aided by mechanical means	4	4	0	0

The last four were all by Abbe's catgut rings. Cause of death: Exhaustion, 1; ligature of hepatic artery, 1; perforation at seat of suture, 1; diarrhœa, 1; obstruction, 1. The operation that should be performed in this class of cases is a complete separation of the end of the duodenum and stomach at the site of constriction. The end of the stomach or duodenum should be closed with a Czerny-Lembert suture, and the distal end of duodenum sutured or buttoned to the side of the stomach, thereby avoiding all of the disagreeable and dangerous symptoms that accompany gastro enterostomy by lateral approximation.

End of duodenum to side of stomach, 4; recovered, 2; deaths, 2. Cause of death, shock, 3; exhaustion, 2; peritonitis, 5; unknown 1.

To Rydygier belongs the honor of being the first to perform this operation. Billroth advanced the operation to great prominence. The *modus operandi* of the various operators is practically the same up to the stage of sutur-

ing the end of stomach. In Billroth's operation the stomach was sutured from the lesser curvature down until only sufficient opening remained to admit of the insertion of the end of the duodenum. The end of the duodenum was then united by a Czerny-Lembert suture to the opening in the end of the stomach. The time occupied for the operation averaged two and a half hours (von Baracz), the greater portion of that time being consumed in uniting the duodenum.

PYLORECTOMY WITH GASTRO-ENTEROSTOMY.

	Cases.	Recoveries.	Deaths.	Mortality per cent.
Suture	24	13	11	45.8
Mechanical means	2	2	0	.0
Suture with mechanical aid	1	1	0	.0
Total	27	16	11	40.7

Rawdon's operation was practically the same, except that bone plates were used to approximate the end of the duodenum to end of stomach. The time consumed in the operation by the Billroth method was so great that all of the patients were collapsed before it was completed; some of them rallied. There was another danger: it was found that at the junction of the line of suture at the end of stomach with the circle of suture approximating the duodenum, gangrene occurred from the strangulation produced by the suture, and a failure of union resulted, increasing the mortality, already great from shock. To avoid these calamities, it was suggested to close the end of stomach and end of duodenum entirely by suture, and make a lateral approximation of the stomach to the duodenum, or jejunum. This has been performed twenty-four times with 13 recoveries, 11 deaths; 45.8 per cent. It is safer and more rapid than any means used for the approximation of the end of the duodenum to the end of the stomach. A still better method is the approximation of the end of the duodenum to the posterior wall of stomach through an incision made for that purpose. Number of this class operated on by mechanical means (anastomosis button), 1; recovery. The procedure by this method should be as follows: place a double clamp on stomach and incise the stomach between; also a double clamp on duodenum with incision between. Transfix the mesentery attached to the pyloric portion with a double-threaded needle; ligate as you would a broad pedicle; excise; continuous Czerny suture of end of stomach; remove clamp and insert continuous Lembert suture, entirely closing the end of stomach. Insert female half of button in posterior wall of stomach as usual; with male half in end of duodenum, press the button together. The operation can be performed in from thirty to forty minutes. It leaves the end of stomach securely closed and the end of duodenum, firmly approximated to a peritoneal surface of stomach, conditions which are favorable for immediate union. This operation has the following advantages: 1. The danger of shock is very materially lessened by the great reduction of time, *i.e.*, from two and a half hours to thirty to forty minutes. 2. The end of stomach is securely closed. 3. There is a uniform pressure in approximation of duodenum to stomach. 4. The danger of peritonitis is lessened because the peritoneal surface has not been exposed to the atmosphere nor manipulated sufficiently to abrade the endothelial layer on its surface; consequently the likelihood of infection is lessened.

Case I. was one of Dr. Alexander Hugh Ferguson's, Winnipeg, Manitoba, who writes as follows: "I wish simply to congratulate you upon your invention of the 'Anastomosis Button,' and to say I used it four days ago in a gastro duodenostomy (end to side) after pylorectomy for cancer. The time from taking the knife to complete closure of abdomen, one hour and twenty minutes. Since the operation there has been no vomiting, no tympanites, restlessness, nor pyrexia. The pulse at its highest was 108. The largest size button suited admirably, and I am sure shortened the time one-half."

August 14th.—"My case of pylorectomy has made an uninterrupted recovery. The button was voided sixteen days and ten hours after operation. He is now eating meat, potatoes, etc., which he has not done for five years."

September 1st.—Patient discharged from the hospital on the twentieth day, apparently in perfect health. He has gained five pounds since the operation.

December 28th.—Patient has gained fifty pounds since operation."

Cholecystenterostomy.—Probably the most difficult of all approximations to make by the suture is that of uniting the gall-bladder to the intestinal tract. The results from experimental research by that method were very unsatisfactory, and the verdict of Gaston, Harley, Colzi, De Paige, and others who pursued these experiments industriously, was that it was a hazardous operation and one very difficult of execution. This opinion was verified by the difficulties and dangers experienced by the pioneers of this operation. It took von Winiwarter sixteen months, with six operations, to perform a successful cholecystocolostomy.

In commenting on cholecystenterostomy by means of suture, Kappeler, Fritzsche, Robson, Courvoisier, Socin, Bardenheuer, and others, say it is an operation very difficult of performance. The number of operations performed by means of suture, up to the present time, is 23, with 8 deaths, 34.8 per cent.; number of operations performed by mechanical means for cholelithiasis, 18, 18 recoveries. Of these 1 bone plate, recovery; 17 Murphy button, 17 recoveries. Number of operations for cancer involving pancreas, duodenum, gall-ducts, and liver, 2, with two deaths. The death in one case reported by Dr. Weir was due to the disease, and not to the method, and occurred two hours after operation; in the other, a case of my own, to a twisting of the bowel upon itself before the approximation was made, as shown in autopsy.

A comparison of these results shows that the operation by mechanical means produces most excellent results; in fact, all that could be desired. It needs no other comment. The explanation of this favorable showing is: 1. That the operation can be performed in an extremely short time (seven to twenty minutes) compared to that by suture, thereby lessening the danger from shock, and also of peritoneal infection from prolonged manipulation and exposure. 2. There is a uniform coaptation of gall-bladder to duodenum which is very favorable to or, better still, insures a union; as there has not been in the human subject nor in the animals experimented on by this method, a single failure of union. The pressure also prevents hemorrhage, which is one of the dangers of suture, as two patients died from that cause. 2. There is an immediate restoration of bile to the alimentary canal, and an assurance that none of it will escape into the peritoneal cavity at the line of approximation.

I believe that the operation of cholecystenterostomy by mechanical means will supersede all other operations on the gall-bladder, in suitable cases. Detailed reports of these will appear in the MEDICAL RECORD shortly.

Entero enterostomy.—In treating this subject we will not take up the various methods of approximation that are now only of historic interest, but will consider the methods that have been employed and reported in operations in the last five years, as will be seen in tabulated statement. These methods we will arrange as in the previous classification: 1, Simple suture; 2, mechanical means; and 3, suture with mechanical aid. The pathological conditions which create the necessity for a resection of a portion of the bowel are of three classes: the order of frequency in which they occur is, 1, strangulated hernia; 2, ileus (intestinal obstruction); (a) strangulation, (b) obturation; 3, intestinal perforations, (a) traumatic, (b) pathological. There will always be a considerable percentage of mortality from the intrinsic dangers of the pathological conditions, aside from the defects of the means employed for their relief. Therefore the problems to be solved are: 1, How can we reduce the intrinsic dangers of the disease? and, 2, How can we minimize the difficulty of the operative procedure *per se*?

In order to decide the first problem, that is, the intrinsic danger, the subject of diagnosis must be exhaustively considered, as the dangers of the disease depend in a large measure upon the failure of early diagnosis. This is particularly true of ileus, and I feel constrained to further emphasize, in connection with this subject, the imperative importance of early and accurate diagnosis, as the result in operations of this class depends more than in any other upon an early recognition of the pathological condition. The difficulty of making a positive diagnosis of the pathological lesion producing the obstruction has been materially diminished by our modern advancements, but is not generally understood nor practised. This necessarily increases the danger to the patient, as the operation is postponed until extreme symptoms manifest themselves. With exploratory laparotomy for ileus, but little difficulty is encountered, although it is occasionally impossible to locate the seat of obstruction. In 190 laparotomies for ileus collected by Schramm, the operators failed in 8 cases to locate the obstruction.

Diagnosis.—There is only one way to obtain good results in ileus—that is, by early diagnosis and operation. In this we must consider every case of ileus as we would an acute strangulated hernia; we know that an early operation for strangulated hernia admits of a much more favorable prognosis than one which is delayed until the intestine is gangrenous. How much more important is it that the early operation should be performed in internal strangulation where gangrene would take place within

the peritoneal cavity! What physician would allow a strangulated hernia to go unrelieved one night? On the other hand, what is the practice of physicians in cases of internal strangulation? They allow not only one night, but two, three, four days and nights to elapse—yes, even to the stage of collapse—before the strangulated bowel is relieved. Only a few days ago I was called to operate in a case of recognized intestinal obstruction of six days' standing; there was not the slightest sign of pulse; the patient's extremities were cold to the trunk; every other respiration was that prolonged heavy sigh that we find in these cases preceding dissolution. It is needless to say no operation was performed.

This is what is called conservatism; *criminal procrastination* is a more proper term. Can we expect, under such circumstances, good results from any method of operation? Do statistics offer sufficient inducements under the treatment by opiates, stomach and bowel irrigations, etc., to justify us in waiting, depending upon a favorable accident to rescue the patient? No. *Expectant treatment in abdominal lesions is only justifiable when the diagnosis of intestinal obstruction is positively excluded.* The only rational outcome to expect from so-called conservative treatment of ileus is death, and in that expectation the physician will rarely be disappointed. The differential diagnosis of intestinal obstruction is not very difficult to make if the symptoms have not been masked by the use of opiates.

To assist in the diagnosis, I submit the following excellent synopsis from von Zoege Manteuffel:

1. Strangulation Ileus.

Pathological Changes.	Clinical Symptoms.
1. Localized meteorismus, dissolution of the strangulated coil.	1. (*a*) Asymmetry of the abdomen; (*b*) localized increased resistance.
2. Ischæmia, paralysis of the strangulated loop of intestine.	2. Complete inactivity of the abdominal wall over the strangulated coil; absence of peristalsis.

In this category are included: 1, Volvulus, agglutination, twisting of the intestine on the axis of its mesentery; 2, strangulation by bands and diverticula; 3, incarceration in pre-formed openings; 4, invagination.

2. Obturation Ileus.

Pathological Conditions.	Clinical Symptoms.
1. Meteorismus produced by accumulation above the obstruction.	1. Perceptible asymmetry, palpable resistance in obstruction of the large intestine, obstruction of the small intestine, diffuse tympanites.
2. (*a*) No pronounced disturbance of circulation. (*b*) Hypertrophy of the intestinal muscles above the obstruction in the chronic form, in the large intestine.	2. (*a*) Peristalsis to be observed or felt. (*b*) Greatly exaggerated peristalsis.

To this group belong: 1, Strictures; 2, twisting of the intestinal axis; 3, obstruction by neoplasms or foreign bodies; 4, compression by tumors from without.

(To be continued.)

The Climate of Southeastern Florida.—It is stated as a remarkable fact, in connection with the extension of the Jacksonville, St. Augustine & Indian River Railway southward to West Palm Beach, on Lake Worth, that, although most of the work was done in the period between April, 1893, and February, 1894—the long subtropical summer of more than six months' duration forming the greater portion of it—not a case of sunstroke or malaria occurred among the one thousand five hundred and more men employed daily during the progress of the work. Many of the laborers were unacclimated, being Italians imported from New York and Scandinavians from the West. The weather during the summer in this part of Florida is said to be pleasant and even exhilarating, the southeast trade-winds serving to moderate the heat to a great extent.

THE ACTION OF RATTLESNAKE VENOM UPON THE BACTERICIDAL POWER OF THE BLOOD SERUM.[1]

From the Pathological Laboratory of the Johns Hopkins University.

By CHARLES B. EWING, M.D.,

Medical Department, U. S. Army.

An apology would be necessary for introducing a subject of this character on the present occasion, if it were not that the loss of life from poisonous reptiles has become so great that it calls forth the best efforts of not only the military surgeon but medical men generally, to lessen it. The mortality in India alone reaches the alarming figure of twenty thousand persons annually, hence it was not a strange coincidence that it should have fallen to the lot of the British medical service, led by Dr., now Sir, Joseph Fayrer, to perform the pioneer work in that part of the globe.

While much has been written upon this subject in general, very little has been said or done in the special line to which this paper relates. At Professor Welch's suggestion we conducted a series of experiments in the pathological laboratory of the Johns Hopkins' University during the spring of 1893, having for their purpose the determination of the action of rattlesnake venom upon the bactericidal power of the blood.

Dr. Welch's attention was directed to the investigation of this subject by Dr. Weir Mitchell. Drs. Mitchell and Reichert demonstrated that the poisonous properties of rattlesnake venom depend upon the presence of proteid substances. These investigators were the first to demonstrate the existence of the so called toxic albumins. In their monograph on the subject as well as from previous observations, it was apparent that the animals killed by rattlesnake venom decomposed with great rapidity, indeed, with such rapidity that Dr. Formad, who contributed an appendix upon the pathological anatomy of animals dead of rattlesnake venom, believed that there was evidence of the spontaneous generation of bacteria.

Dr. Formad thought it impossible for the bacteria to make their way into the circulation and multiply so quickly. This seemed so improbable to Professor Welch that he suggested to Dr. Weir Mitchell the importance of having this point worked up. Dr. Mitchell kindly gave us a certain amount of poison. We were, however, fortunate enough to obtain a live rattlesnake of the diamond species, known as the Crotalus Adamanteus, from which the fresh venom was obtained and used in preference to the dried poison supplied us

It will not be out of place to recall briefly that the order Ophidia, of the sub-class Reptilia, is divided into three subdivisions: 1. The Ophidii Colubriformes, or innocuous snakes. 2. The Ophidii Colubriformes Venenosi, or poisonous Colubrine snakes. 3. The Ophidii Viperformes, or Viperine snakes, poisonous.

To the last subdivision, viperine snakes, belong the Crotilidæ or rattlesnakes, called by Fayrer "Pit-vipers," being distinguished from the Viperidæ or vipers proper, by possessing a pit or depression between the eye and the nostril in the loreal region; a triangular broad head, and thick body of variable length.

The Crotalus is distributed widely over the globe and all are terrestrial except in India, where quite a number of genera are arboreal; all, however, lack all semblance of the horny scales or rings at the tip of the tail, known as the "rattle," except the species called Halys, where the tail terminates in merely a rudimentary horny spine.

It is of interest to note that the Indian Crotolidiæ are not so venomous as their American congeners, though Asia has a very deadly species known as the Calloselasma Rhodostoma resident in Java and Siam; while South America is represented by the well-known Jararacca or Craspedocephalus Braziliensis. Australia and Africa

[1] Read before the Association of Military Surgeons, Washington, May 2, 1894.

likewise contain ophidians of this class, but they are little known.

The crotolidiæ of the United States are represented by ten species and three sub-species, all being equally poisonous, so far as we now know. Of these, the adamanteus has three sub species, one of them, the adamanteus proper found in this country, extending from North Carolina to Florida; a second, the Atrox, resident in the Indian Territory and Texas, also throughout that stretch of country extending to Sonora and Southern and Lower California; and a third called Scutulatus, known only to Arizona.

We had in view in the first place to test the question as to whether the blood of animals killed by rattlesnake-poison had lost any of its germicidal power.

We used Dr. Weir Mitchell's noose for securing the snake, and with a sterilized saucer thrust into the mouth of the animal, we collected the venom. In this way we had no difficulty in getting from 0.5 to 1 c.c. of nearly clear, slightly straw colored fluid, quite sufficient for our purposes. This was diluted with an equal quantity of sterilized physiological salt solution, and 0.25 to 0.5 of this mixture was inoculated subcutaneously, under antiseptic precautions, the dose varying according to the time we wished the animal to live. This was usually from one-half to one hour and a half, though in one or two cases, three hours after the injection.

The injections were in all cases given subcutaneously, sometimes beneath the skin of the abdomen and at other times in the groin. The lesions differed somewhat according to the site of injection; when made beneath the skin of the abdomen, there were most extensive peritoneal hemorrhages, whereas, when the injections were made in the thigh, these lesions were less extensive, although not absent; here the most striking effect noted, beside the deeply discolored integument surrounding the point of injection, were the underlying hemorrhages into the muscles.

The important lesions were briefly these: most extensive hemorrhage, with disintegration of tissue and actual necrosis of tissue for a wide distance around the point of inoculation, with ecchymoses in other parts of the body, particularly in the serous membranes. Another point which served our purpose admirably, is that the blood does not coagulate after death or coagulates only feebly and after a long interval. We therefore had no difficulty in collecting a sufficient amount of the fluid blood, and we did so by withdrawing the blood in less than a minute after the animal breathed its last. We exposed the heart at once, and with sterilized instruments made an incision in the right auricle and with a sterilized pipette we aspirated from the right heart, and then passing the pipette down into the abdominal vena cave, we secured sometimes as much as seven or eight c.c. of blood. This blood was collected in a sterilized test-tube and put in the refrigerator. After twenty-four hours, the red blood corpuscles had settled, sometimes a small, soft, dark coagulum had formed, and there was a layer of clear serum.

The usual statement is that the blood does not coagulate. It looks as if it did not coagulate, and as though there was merely a sedimentation. But there is in fact an extremely thin clot, which does not retract from the sides of the test-tube. It is an extremely viscid, sticky coagulum, which adheres to the platinum needle inserted into it. We pipetted off the clear serum after twenty-four hours, usually collecting 0.5 to 1.5 c.c. The organisms which were used to test the germicidal powers of the serum, were the bacillus coli communis and the bacillus anthracis. Professor Welch selected the bacillus coli communis because that is an organism which is normally present in the intestine and also one with which he had experimented upon with normal serum. He took the bacillus anthracis because that is a classic organism in regard to the action of serum. The results were uniform and striking. As a rule, we made a control experiment with normal serum; thus we killed a healthy rabbit and withdrew the serum in the same way, collected the same quantity and inoculated, at the same time, as a parallel control, tubes with the bacteria to be tested. The cultures were twenty-four to forty eight-hour cultures. Our bacillus anthracis was obtained in suspension from the spleen of an animal recently dead of anthrax. We wished to obtain the anthrax bacillus free from spores, and thought it better to take it fresh from the animal. Similar results were obtained also with twenty-four-hour anthrax cultures grown at room temperature. We made a suspension in salt solution of the organisms and inoculated a known quantity, one to two platinum loops of the suspension into the serum tube. Then we made roll cultures.

The following tables, drawn up by Professor Welch, represent only a certain number of our experiments and are much abbreviated for the sake of clearness.

BACILLUS ANTHRACIS.

NORMAL SERUM.

No.	Number of Bacilli Inoculated.	After Twenty-four Hours.	After One Week.
1A	485	0	0
1B	8,512	0	0
1C	210	0	0
2A	5,292	0	0
2B	1,628	0	0

VENOM SERUM.

No.	Number of Bacilli Inoculated.	After Nineteen Hours.	After Twenty-four Hours.
1A	8,512	Countless	
1B	25		3,233
2	68		250,000
3	3,292	Countless	
4	3,292	Countless	
5	3,292	Countless	

BACILLUS COLI COMMUNIS.

NORMAL SERUM.

No.	Number of Bacilli Inoculated.	Immediately.	After Twenty-four Hours.	After Forty-eight Hours.	After One Week.
1A	250,000	256	157	Countless	Countless
1B	175,000	188	50	Countless	Countless
2A	29,161	53	0	0	0
2B	3,150	18	0	0	0
3	9,990	13	38	625	Countless
4	84,947	258	0	0	0

VENOM SERUM.

No.	Number of Bacilli Inoculated.	Immediately.	After Twenty-two Hours.
1	800,000	1,077	Countless
2	3,150	6	26.000
3	16,560	32	Countless
4	9,990	35	Countless
5	84,947	284	Countless
6	84,947	231	Countless
7	84,947	182	Countless

With the bacillus coli communis, it will be observed that, in the case of normal serum, we inoculated 250,000 bacteria. Immediately afterward, there were 256 colonies. After twenty-four hours only 157 colonies. In other words, there was not only no development, but an actual diminution in the number of bacteria. If the organisms are not all killed at the end of twenty four hours, the germicidal power ceases and those which remain multiply. After forty-eight hours the colonies were countless. In the second experiment we inoculated 175,000 bacteria, which represented 188 colonies immediately. After twenty-four hours, there are only 30 colonies, and in forty-eight hours, they were countless. Taking a smaller number of bacteria, 29,161, there were immediately 55 colonies, after twenty-four hours, none, after forty-eight hours none,

after one week none. In other words, in twenty-four hours the normal serum had destroyed 29,000 bacteria.

These experiments were uniform in results, and point to one conclusion, that the blood of rabbits killed in one-half to three hours after subcutaneous inoculation with rattlesnake venom, has lost its germicidal power. This is of considerable interest, for it is an indication of a very profound alteration in the blood. This germicidal power of the blood is one of very great significance, on which many of the modern theories of immunity depend.

It is of special interest to ascertain under what conditions the germicidal properties of the normal blood-serum are at their highest and in what way these properties affect the composition of the blood.

The principal workers in this field have been Von Fodor, Nuttal, Wassermann, Kitasato, Buchner, Ogata, Hankin, and others. Von Fodor's work had reference to the composition of the blood and was intended to show that arterial has a more destructive action on bacteria than venous blood, and also that fresh blood has a more destructive action than that which has been standing for some time. It was also found that the germicidal power of the blood was weakened in an atmosphere of oxygen or carbonic-acid gas, but the removal of gases from the blood had no appreciable effect.

A series of experiments showing the effect of moving and stationary blood upon bacteria by means of small globes containing blood, some of which were kept in constant motion and others quite stationary, resulted in no appreciable difference being observed.

Temperature affected very materially the bactericidal power of the blood, which increased with the rise of temperature from 38° to 40° C., and then gradually diminished with the fall.

Von Fodor is of the opinion that the individual predisposition of an animal to an infectious disease stands in close relationship with the germicidal power of the blood. A second series related to the influence of drugs on the power of blood to destroy germs.

Hydrochloric acid had no effect; tartaric acid and quinine respectively, produced a marked decrease. A slight increase was produced by common salt and carbonate of ammonium, but a more marked effect by the phosphate of sodium, while the carbonate of potassium and sodium showed a very remarkable increase. From these experiments the deduction was made that the bactericidal power of the organism was raised by any drug which increased the alkalinity of the blood. The third series verified the conclusions regarding the alkalization of the blood. Of eight rabbits inoculated with anthrax all died, while of nineteen which had been previously injected with solution of soda, only three died. A majority of the sixteen remaining were perfectly free from disease, only a few being fatally affected.

Up to this time, however, the doctrine of phagocytosis as advanced by Metchniknoff held sway, when Nuttall struck the first severe blow to this theory. He, in his most excellent inaugural dissertation at Göttingen in 1890, showed that the destruction of virulent bacteria in the blood of animals by the leucocytes, was not at all essential, but that the serum of blood free from all cellular elements possessed this power to a degree equal to the blood in its entirety.

Nuttall's work is graphically shown in some twenty-eight tables in his "Beiträge zur Kenntniss der Immunität." He here proves very conclusively, that in the blood bacteria presented marked evidences of degeneration before being taken up by the wandering cells, or leucocytes. It was also seen that the bactericidal power of the blood of different animals varied and that while in some certain bacteria were promptly killed, in others these were simply restrained for a time or not affected.

Buchner, Lubarsch, Nissen, Stern, and Prudden have practically verified these observations. Buchner particularly, in his experiments upon dogs and rabbits verified the findings of Nuttall, but went even further and proved that the bactericidal power of the blood in these animals did not at all depend upon the cellular elements, but resided in the clear serum which separated from the clot, after the blood had stood a while in a cool place. He also demonstrated that the germicidal action of blood and serum were destroyed by exposure for an hour to 55° C., or by heating to 52° C., for six hours or to 45.6° C. for twenty hours.

Alternate freezing and thawing did not destroy the bactericidal power of serum, but it was diminished or completely checked by dialysis with distilled water, or by extreme dilution with the same. He preserved the antibacterial action of the serum by making an equal dilution with a .6 to .7 per cent. of sodium-chloride solution and was led to believe that the activity of the serum was greater alone than when the cellular elements of the blood were present, hence he concluded that the active element is a living albumin, having as an essential constituent an alkaline base. This albuminoid substance is thought by Hankin to be identical with his "globulin," isolated from the spleen and lymphatic glands.

According to the views of these experimenters the germicidal power of the blood resides in the serum alone, and phagocytosis is but a secondary process, the leucocytes taking up the bacteria only after they have been rendered inert by the germicidal power of the serum of the blood, and certain other fluids of the body. For our purpose, however, it is not necessary to insist upon the humoral as opposed to the phagocytic doctrine of immunity. All that concerns us is the recognition of the bactericidal power of the blood serum under certain conditions.

The loss of this normal germicidal power helps us to explain the varying rapidity with which post mortem decomposition sets in. It is well known that persons dead of different diseases decompose with varying degrees of rapidity. We cannot explain this differing rapidity of decomposition simply by variations in temperature, for under the same external conditions one body will be decomposed in comparatively few hours and another may remain undecomposed for several days. We selected the animals killed with rattlesnake venom because it is well known that they decompose with great rapidity. The bodies of human beings killed by snake venom are also said to decompose with great rapidity.

The results of our experiments furnish a satisfactory explanation of this phenomenon. The blood at the time of death and even before death, has lost all or nearly all power of resisting the invasion and multiplication of certain bacteria, so that the bacteria of putrefaction, which are normally present in the intestine, develop with astonishing rapidity and even before the animal is cold, produce this wonderfully rapid decomposition. Our experiments are also suggestive as regards certain secondary and mixed infections. The toxic proteids of snake venom belong to the same class of poisons as those formed by toxic bacteria, such as the bacillus of tetanus, of diphtheria, etc.

It is easy to suppose that these infectious diseases may cause a diminution of the germicidal power of the blood against secondary invaders, of which common examples are the pyogenic bacteria present often in our mouths and intestinal canals, and which in an individual whose resistance is lowered by a loss of the germicidal power of the blood, may grow and multiply. In other words, we can understand better the causation of many of these secondary infections.

The Paris Water Supply.—One of the main aqueducts of Paris has been closed for repair of a leak, and the city is now mainly dependent upon the Seine for its water supply.

Cremation in France.—The average number of cremations in France for the first three months of 1894 was ten a day, an increase of about twenty per cent. as compared with the same period of last year.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, May 26, 1894.

INVESTIGATION OF THE CITY INSANE ASYLUMS.

THE Female Department of the New York City Asylum for the Insane has recently been made the object of a newspaper attack, and in consequence the State Commission in Lunacy has been asked by the Mayor to investigate that institution. May 28th has, we believe, been fixed for beginning the investigation. The charges made against the institution appear to be, when exhumed from the distressing intricacies of unnumbered columns of irrelevancy, first, that the female patients have been unwisely removed from bad quarters on Blackwell's Island to worse ones on Ward's Island; and secondly, that they are improperly housed, clothed, fed, and treated in their present quarters.

The wisdom of the transfer from Blackwell's to Ward's Island is of course a matter of opinion, but there are certain matters of fact in connection with the newspaper account of the transfer that deserve notice as showing the animus of the newspaper criticism. It is said that the buildings now occupied by the female insane on Ward's Island were declared worthless after being vacated by the Immigration Board some years ago, and that they have steadily deteriorated since then, and are now occupied without being in any way repaired. In point of fact, all but one of the buildings now occupied by the female insane were fitted up for the male insane soon after the city acquired the emigration property, and have been continuously occupied by the male patients until vacated to make room for the females. The exception is the Verplank Hospital, a building which is said to have cost the State $800,000. This building has, it is true, stood vacant since the emigration patients left, but far from being "unrepaired," it was for some months in the hands of the contractors, who plumbed it throughout, put in wires for the electric lights, provided it with fire-escapes, and made such general repairs as were necessary to put it in excellent condition for occupancy. It is to day one of the most substantial buildings in the department. Whether it is adapted to the care of the insane (having been originally intended for general hospital purposes) is another matter, but we can testify from personal inspection that it is in no sense a "loathsome, rotten structure." The condemned buildings, which are said to be "occupied unchanged," were in reality burned or torn down about two years ago, preparatory to the construction of the new buildings, which are now practically completed, but not yet quite ready for occupancy. The débris resulting from the destruction of some old buildings and the repair of others, and the building of new ones, some of it still subject to the orders of contractors and so unremoved, constitutes the "ruins" the sight of which so grieved the sensitive soul of the newspaper writer. Indeed, most that is said about the disorder without or within the institution may be easily attributed to the measure of confusion necessarily incident to the transfer of an institution numbering more than two thousand inmates from long-established to new quarters, a transfer which, it may be added, is still incomplete. These details, not in themselves essentials, are worth stating as evidencing the animus and spirit of the newspaper attack. Such inaccuracies about matters easily ascertained suggest either carelessness or worse in the investigation which has led to the exposé, and must seriously invalidate testimony from the same source in all its bearings.

Leaving aside such temporary shortcomings as are necessarily incident to the removal, we do not care at the present to comment at length upon the internal administration of the asylum, inasmuch as an official investigation has been ordered. It is our opinion and expectation, however, based upon a thorough knowledge of the institution as conducted at its former site, and upon several recent visits of inspection made by a member of our staff (both before and since the exposé) to Ward's Island, that the investigation will result in a complete vindication of the Superintendent and General Superintendent of the institution. Holding this view, and knowing that the newspaper tirade will continue until the investigation is over, we cannot but regret the tardiness of the State Commissioners in Lunacy in beginning the investigation, which we feel sure will relieve the management of the asylum from the fire of unjust censure.

While we thus believe that such matters as lie within the control of the asylum superintendent have been efficiently conducted, we are equally convinced that there are many matters beyond his control regarding which reforms are radically needed. We have long known and have often said that the insane wards of the city are inadequately provided for, as to shelter, food, clothing, and attendance. But we have also known that the city provides only $2.80 per week at the very most for the maintenance of each of these insane wards, whereas the maintenance of our State asylums has often required four, five, or even six dollars per week for each inmate. The real question to be investigated, therefore, is not whether the authorities of the city asylums care for their patients on the scale of the State asylums, but whether they care for them to the full extent of the purchasing power of the money at their command. If it can be shown that the $2.80 appropriated for the weekly care of each patient is wisely and economically expended for the purpose intended, then the asylum superintendents and the Commissioners of Charities and Correction must be exonerated from all responsibility for deficiencies of lodging, food, clothing, or attendance supplied their charges; for it is matter of common knowledge that these authorities have constantly solicted from the Board of Apportionment more money for the insane, and that a deaf ear has been turned to their appeals. To the Board of Apportionment, then, the investigation should turn, to inquire why appropriation for a rich city's most depend-

ent wards is restricted to such niggardly limits. When that question is answered we shall have gotten a step on the road to reform. Wherever else dereliction of duty may or may not be found, it will be difficult to justify the action of the Board which imposes such ungenerous restrictions upon the most pitiable class of dependants that any community is called upon to care for.

It has been repeatedly said that the people of New York stand ready to provide liberally for the insane. More than this is true. The people of New York—that is, the tax-payers—*do* provide liberally for them; but each year half a million dollars of the sum they are assessed for that purpose must, according to the existing law, be diverted into the State treasury for the care of the insane in the State hospitals, and for this sum the city receives no return whatever except the privilege of caring for its own insane independently, caring for them about half as well as the State insane are cared for. The people manifestly have a right to inquire why their money is thus diverted from wards that so sadly need it. Why should the city care for its own insane and then pay, in addition, the cost of maintenance of forty per cent. of all the insane in the State outside the city? Would it not be better to enter the State system, when by so doing we could have our insane cared for about twice as well as at present without additional cost? The State system is by no means perfect, it is true, but there is reason to hope that the searching criticism it has been subjected to the past winter will result in greatly improving it, and even as it stands it must be conceded to be far better than our city system. The law provides that the city may enter the State system whenever the city authorities so desire. Who stands in the way of this transfer? If the coming investigation of the Ward's Island Asylum leads to the explicit answering of this question, it will clear the way for reforms in our method of caring for the insane that will be appreciated not more by the unfortunates themselves than by the much maligned authorities who are directly responsible for their custody.

MARRIAGE AND VENEREAL DISEASE.

THE medical profession is quite familiar with the discussions that have appeared relative to the infectiousness of old cases of gonorrhœa and of the injury done to innocent wives by marriage with such sufferers. The view at the present day is, we believe, that these uncured gonorrhœas are the cause of many cases of chronic pelvic troubles, endometritis, salpingitis, etc. Instances in which men who have had syphilis have communicated the disease to their wives and children are painfully familiar in every physician's practice.

These very unpleasant but extremely important facts have been utilized lately by a lady novelist in a book which has had extreme popularity in this country and England. "The Heavenly Twins" preaches and teaches mainly this doctrine, that men of the world who have led worldly lives are extremely liable to have been infected with a venereal disease at some time in their premarital career. Hence, young girls ought not to marry them. Furthermore, young ladies should be made acquainted with the habits and the code of morals of the young men of the day, and should not allow themselves to be surprised into falling in love with characters who are dangerous physically even if they are reformed morally. No amount of mutual love, she argues, will last if the husband proves to be specifically infected, or if the wife develops the ailments associated with chronic disease of the uterus and appendages. The sterility of the male as a result of venereal infection, and the consequent inability to gratify the maternal instinct, is an argument upon which the limitations of polite fiction probably made it impossible to dilate.

We do not know that anything can be said against the case so eloquently and ingeniously presented by Sarah Grand. Critics have said that it was in bad taste, and perhaps physicians would say that the argument appeals only to a certain not very large class of society. Syphilis is common enough among the poor, but the tragic marital consequences are perhaps most seen among the richer classes.

FORWARD.

A WRITER in *The Woman's Medical Journal* who signs herself from Louisville, Ky., gives some very extraordinary advice under the head "Forward." She says:

"The physician to-day must be on the alert for patients. Hospitals, asylums, and infirmaries and drug stores are strongly competing for patients. In them from ten thousand to fifteen thousand young physicians are being graduated, to enter new and inviting fields of labor. All these facts emphasize the argument that unless a man is peculiarly fitted for the profession he had better seek other business. If a physician fails to make a living, it is a bad failure. Business men don't want doctors, and it is hardly the thing to undertake manual labor. The doctor in active practice must have *push and audacity*. He must anticipate—*anticipate*, and carry his ammunition with him. In a crowded church he should be prepared with restoratives for a sudden case of asphyxia. The same in a theatre and other crowded places. The quick, kind, and affectionate doctor is the successful one. He must be a man of resources, and able to make medicines and tools out of nothing. He must do business economically, get his pay commercially, or his work will turn out charity. Diagnose your case quickly and then apply its remedy. Keep your own medicines."

There is a "breeziness" and "go" about this that is refreshing to the point of taking one's breath away. It must have been quite such a type of doctor who went to the theatre in this city a few months ago. It was a somewhat mixed performance, and after one of the acts the curtain was rung up and the leading comedian came to the front of the stage. He looked very anxious and worried, and in a distressed voice asked if there was a physician in the audience. Immediately up jumped one of the Louisville lady's models and said, "I am a physician." "All right," said the comedian, "don't go away till I get through with this song." The too alert practitioner sat down.

The writer in the *Woman's Medical Journal* is no doubt correct in saying that physicians must be always ready. But she neglects the important thing; he must be well prepared, in the first place; he must diagnose his case not quickly, but carefully and skilfully; he must show, not that he is alert to push himself into every place,

but that he understands his calling, its exacting requirements, and its arduous responsibilities.

We have noticed before this that women physicians were too ready to attach themselves to the numerous fads and dogmas which run so closely to charlatanry. And *The Woman's Medical Journal* does its sex no credit in publishing such pernicious rubbish as that which we have quoted.

News of the Week.

Medical Association of the State of Alabama — In a recent issue it was stated that the annual meeting of this Society was held in Mobile on April 16 and 19, 1894. The notice should have read—the *next* annual meeting *will be* held in Mobile, April 16 to 19, 1895.

The Accouchement of the Duchess of York is looked for some time in June.

A Police Surgeon Makes a Man Grow.—The following extract from the proceedings of the Police Investigation does not reflect credit on the medical part of our police system. Mr. Goff, counsel for the investigation committee had the following colloquy with a witness:

Q. Was Joe Cohen appointed? A. Yes.

Q. Did it cost him anything? A. Yes, $205.

Q. To whom was the money paid? A. The doctor who examined him got $30.

Q. What became of the rest? A. It went to Police Headquarters. . . .

Laughter was caused by the next few questions, put with quizzical significance by Mr. Goff. He asked if Cohen was undersized, and the witness replied that he was.

"Before the surgical examination?"

"Yes, he was half an inch too short."

"But by the time he had gone through the surgical examination he had grown half an inch?"

"Yes."

Not Consistent.—The *Medical News* has been a most aggressive and eloquent opponent of institutional medicine. But now it says: "The time has arrived when the State of Pennsylvania must make similar provision for her large contingent of epileptics. The Legislature can no longer fail to heed the appeals from County Medical Societies and the State Medical Society for the establishment of one or more epileptic colonies."

The Gouverneur Hospital.—The sum of $200,000 has been appropriated for the construction of additional buildings.

Niagara University.—The annual Commencement of the Medical Department was held on the 9th inst. The degree of M D. was conferred on fourteen candidates. The valedictory address was delivered by Harlow C. Curtiss, M.A., Professor of Medical Jurisprudence.

Theodor Billroth's Successor.—To bend the bow of Ulysses is proverbially a difficult undertaking, and to succeed a Billroth in the chair he adorned is an object of ambition to which few indeed legitimately aspire. Still, the duties of that chair have to be discharged, and the Vienna school has just taken the primary steps to fill it. At a meeting of its medical faculty three candidates were nominated for the post: *Primo loco*, Vincenz Czerny, Professor of Surgery in the University of Heidelberg; *secundo loco*, Karl Gussenbauer, Professor of Surgical Pathology and Therapeutics in the University of Prague; and *tertio loco*, Johann Mikulicz, Professor of Surgery in the University of Breslau. There is, we believe, little doubt that the first-named surgeon will be appointed.—*The Lancet.*

Medical Society of New Jersey.—The next annual meeting of the Medical Society of New Jersey will be held on the fourth Tuesday in June, 1894, at Lake Hopatcong.

The Annual Meeting of the American Medical Publishers' Association will be held at White Sulphur Springs, West Va., Friday and Saturday, August 3 and 4, 1894.

Professor W. W. Keen, of Jefferson Medical College, Philadelphia, has been appointed, by President Cleveland, as a member of the Board of Visitors at West Point Military Academy.

Mrs. Humphrey Ward, the novelist, has writer's cramp.

Dr. Elijah S. Elder, of Indianapolis, died May 18th. He was president of the Indiana Medical Society, and was fifty-three years old.

Connecticut has a New Law regulating capital punishment, which requires the execution of the death penalty privately within the State prison, before sunrise. It still employs the ancient, inexpensive, and very certain method of hanging.

The First Meeting of the Pennsylvania State Medical Examining Board will be held June 11th, after the Commencement of the Medical Department of the University of Pennsylvania, which takes place June 7th.

The Medical Department of the Columbian University, Washington, D.C., held its annual Commencement April 24th. There were twenty-seven graduates.

To do Justice.—Dr. Seth Scott Bishop, M.D., of Chicago, writes: "Will you kindly do me the justice to publish my reply to your paragraph concerning me on page 596 of the RECORD for May 12th?

"My prize essay on hay fever for 1893 was written without any knowledge of Dr. Tyrrel's work. If I had known that he had written on the subject I should have gladly availed myself of any valuable facts brought to light, and should have given him full credit, as I did with the thirty-eight other authors quoted. Indeed, I stated that 'I had taken pains to give each investigator ample credit by liberal quotations.' After writing the essay I learned that Leflaive had preceded me in this line of study by at least four years, and gave him due credit, so that, happily, there is no occasion for any dispute between us concerning priority. We are both antedated. We have arrived at the same results through independent investigations, as often happens, and I do not want, and have not received, any credit to which I am not fairly entitled."

State Board of Medical Examiners of New Jersey.—A special meeting of this Board for the examination of candidates desiring to practise medicine in this State will be held in the Capitol, at Trenton, on the third Tuesday in June (the 19th), and it will be the last meet-

ing for the examination of candidates held under our present medical law, as the new law enacted at the recent session of the legislature goes into effect July 4, 1894. This new law requires all candidates to have a competent common school education, to be graduates in medicine and surgery which they shall have studied at least four years, and upon which they shall have taken three full courses of lectures, before they can be admitted to the examination for a license, and then all will be subjected to the same examination; it also empowers the Board to accept, in lieu of an examination, the certificates of other State Examining and Licensing Boards having similar requirements.

Dr. J. B. Murphy.—The Chicago Academy of Medicine tendered a banquet at the Union League Club, Friday evening, May 18th, in honor of Dr. J. B. Murphy, on the occasion of his return from Europe.

Jefferson College held its Commencement exercises May 9th, and graduated a class of one hundred and sixty-three. The trustees conferred the degree of LL.D. upon Professor William Goodell, M.D.

The Medico Chirurgical College graduated the largest class in its history on the 11th inst., forty-four students receiving their medical degrees.

New Women Physicians.—Fifty women have received the degree of Doctor of Medicine at the Commencement of the Women's Medical College of Pennsylvania.

A Pension Fund for Employees of the Health Department.—The Governor has signed the Lawson Bill, establishing a pension fund for the physicians, nurses, clerks, and other employees of the Health Department who have served a term of twenty years, and also for the families of employees dying in the discharge of duty. The fund from which the pensions will be paid is to be made up of the fines and penalties collected for violations of the city health laws, and of the fees paid for searches of the records.

One Hundred and Five Years of Age.—According to the *Journal of the American Medical Association*, Mrs. Hannah Chard, of Glassboro', N.J., was one hundred and five years of age on April 20th, having been born at Brandywine in 1789. She is still able to go out, and has one hundred and eighty grandchildren and great-grandchildren.

Columbia Medical College.—The Commencement exercises of the Columbia Medical College, followed by the Faculty dinner, took place May 3d. General prize of $50 awarded to Gottlieb Werhle; clinical medicine to W. S. Washburn; clinical surgery, Miss C. Kiefe.

Decision Against Compulsory Vaccination.—A short time ago we referred to the case of two Brooklyn expressmen who were practically imprisoned because they refused to be vaccinated. They were released on a writ of habeas corpus. Justice Gaynor subsequently rendered a decision adverse to the Board of Health. His decision is important, and we quote it in part. He says: "If the Commissioner had the power to imprison an individual for refusing to submit to vaccination, I see no reason why he could not also imprison one for refusing to swallow some dose. But the Legislature has conferred no such power upon him, if, indeed, it has the power to do the like. Chapter 661 of the Laws of 1893 (Section 24), empowers all health boards to 'require the isolation of all persons and things infected with or exposed' to contagious or infectious diseases. There is no claim that the petitioners are infected, or have been actually exposed to infection. But even if they were subjects for isolation by reason of infection or exposure thereto, they could only be detained while such, and not indefinitely until they yielded their bodies to vaccination. The same act directs health boards to provide vaccine virus, 'and at all times provide thorough and safe vaccination for all persons in need of the same.' This falls far short of authorizing the imprisonment of those who refuse to be vaccinated. . . . If the Legislature desired to make vaccination compulsory it would have so enacted.

"My attention is also called to Section 5 of Title 12 of the Charter of Brooklyn, which is that in the presence of great and imminent peril of the public health, it shall be the duty of the Commissioner of Health 'to take such measures, and do and cause to be done such acts, and make such expenditures beyond those duly estimated for and provided, for the preservation of the public health from such impending pestilence, as he may in good faith declare the public safety and health to demand, and the Mayor of said city and the President of the Medical Society of Kings County shall also in writing approve.

"This does not mean that the Commissioner may take unlawful measures or do unlawful acts. It must be interpreted in the light of the Constitution and settled legal principles and safeguards. It does not confer on the Commissioner the right to imprison any more than to take life.

"I need not discuss here the right to isolate or quarantine in times of pestilence. That right grows out of the overwhelming necessity of the case and has its limitations. It is not being exercised here, for the petitioners are not being held in isolation as subjects of danger to the community, to be released when their bodies are no longer sources of infection, but they are being forcibly confined because they refuse to submit to vaccination and until they do submit thereto. The petitioners are discharged."—*The Brooklyn Anti-compulsory Vaccination League.*

Licenses must be Recorded in Alabama.—The Supreme Court of Alabama holds, in the case of Nicholson *v.* State, decided February 8, 1894, that the requirements of the Alabama Code, with regard to the recording of certificates, or "licenses," are mandatory and vital. It is provided that every certificate of qualification authorizing any person to practise medicine in that State, which shall be issued by any authorized board of medical examiners, shall be presented to the probate judge of the county in which such person resides, who shall officially indorse the same, seal it with the seal of the county, and cause it to be recorded in a book kept for the purpose. The very fact that no time is fixed to comply with these requirements, the court says, is a strong argument in support of the position that until they are complied with the so-called "license" is waste paper conferring no right perfect or inchoate.—*Journal of American Medical Association.*

Curious Bequest of a Physician.—The late Dr. G. S. Moore, of Glasgow, has bequeathed the sum of $225,000 to found a convalescent home for nurses.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 3, 1894.

D. B. St. John Roosa, M.D., President, in the Chair.

Electric Light Plant for the Academy.—The trustees recommended that a complete electric light plant be placed in the building, at an expense not to exceed $1,800. Before putting the motion to adopt this recommendation, the President stated that the expense of the plant would amount only to about that of lighting the building one year by electricity from the street. The motion was adopted.

Committee to Advise with the Constitutional Convention.—The council recommended that it be given power to appoint a committee of three to advise with the approaching constitutional convention regarding medical matters.

The President thought this was a matter of great importance, for, by a singular oversight, the medical profession was not represented in the membership of the convention, and if they would not be ignored there as they had been in the past they must be present to make their wishes known.

Dr. Armstrong thought it was customary for the president to appoint committees, and moved that the recommendation of the council be adopted with that amendment, which was done.

Report of Special Committee on Registration of Marriages and Births.—Dr. Alexander Hadden said that before the special committee appointed at the last meeting could take action further than write the Governor, urging his veto, the defective bill relating to the report and registration of marriages and births had been made a law. What was desired was a bill making the registration of marriages and births so easy as to be universal, and so exacting as to constitute documentary evidence before the courts. The present law, as the past one, not only failed to meet these requirements, but was unjust to medical men, to the public, and even to those who kept the records, because it simply wasted their time. As there was nothing more for the committee to do, he asked that it be discharged.

Amendment to the By-laws Proposed.—Dr. Grandin offered an amendment to the by-laws, to be acted upon at the next meeting, making the chairman of the committee on nurses and the chairman of the house committee members ex-officio of the council.

The Adoption by the Academy of a Nomenclature for the Different Classes of Infectious Diseases.—Dr. William H. Thomson read the paper. Medical terms, he said, became important as such in proportion to their influence upon conduct. When the wrong use of terms immediately disturbed the affairs of a household, and seriously altered the natural relations of its members to one another, or alarmed an entire neighborhood, or emptied a town, or greatly deranged the commerce of a country, it certainly behoved the medical profession to endeavor to prevent all such misunderstanding by making the meaning of terms as definite as possible. Instead, however, of this having been the case in the past, there was not a more unpleasant feature of the history of medicine than the controversy which had grown out of the use of terms intended to be descriptive of the nature of infectious diseases. No word could escape entirely being associated with its primary meaning; the derivation of descriptive names, particularly, was never wholly lost to view. To spread by contagion meant to spread by touch, and it was impossible to disabuse the mind, whether medical or non-medical, of certain suggestions connected with this first significance of the term. As soon as a disease was known not to spread by touch it was inferred to have no relation whatever with contagious diseases. Asiatic cholera, for instance, was easily shown not to be a contagious disease, because in every epidemic persons were known to have fallen victims to it who had not come in contact with the sick, and the conclusion was reached that therefore cholera had nothing to do with human intercourse, any more than had ague. As it was then observed to be neither contagious nor miasmatic, it was proposed to call it infectious, but this only served to make the conception of its truth more vague than ever. Vague fear was the mother of panics; vague terms were the most potent generators of vague fears.

The subject had of late assumed quite a new phase and importance, by the fact that the progress of medicine had led us to add to the list of specific infectious diseases tuberculosis and ague. If we should pronounce tuberculosis infectious, the public would have a right, in view of the common understanding of the term, to ask what we meant. Enough was known at present by the profession to tell the world just what infection was, and what were the chief modes of its conveyance.

A Classification Suggested. — Dr. Thomson then suggested the following classification for infectious diseases, hoping that it would invite discussion by the profession upon the adoption of a definite nomenclature descriptive of the various classes of infectious diseases.

1. Infectious diseases are due to the presence of their respective living micro-organisms in the body. 2. Infectious diseases are divisible into three classes: *a*, communicable, *b*, non-communicable, *c*, septic. 3. The communicable diseases are those whose origin is from an animal body, examples of which are small-pox, asiatic cholera, and tuberculosis. 4. The non-communicable infectious diseases are those whose origin is not from an animal body, but from a place or thing, examples of which are ague, yellow fever, and miasmatic diseases in general. 5. The communicable diseases are divisible into two classes, according to the ordinary modes of their communication: *a*, into the contagious, *c*, into the non-contagious communicable diseases. The contagious communicable diseases are those in which simple proximity to the sick is sufficient to communicate the infection; examples of which are scarlet fever, measles, small-pox, diphtheria, mumps, etc. Isolation of the sick in these cases is, therefore, needful to prevent infection. The non-contagious communicable diseases are those in which the communication is not by simple proximity to the sick, but through intermediate means of communication. Isolation of the sick with them, therefore, is neither needful nor effective in comparison with measures directed against intermediate means of infection; examples are, typhoid fever, asiatic cholera, and tuberculosis. 6. The septic infectious diseases are those in which infection is introduced through a wound or abrasion; examples are, erysipelas, hydrophobia, tetanus, etc.

Lastly, all infectious diseases can be prevented by measures of disinfection applicable to each. If the public could be made to understand that all infectious diseases were due to micro-organisms primarily, they would more fully comprehend and appreciate the significance of disinfection.

Only Diseases of an Animal Source Could be Communicated to Others.—Ague and yellow fever were not derived from an animal source, and therefore were non-communicable. It was fitting to direct attention to the fact that all classes of infectious diseases were capable of being disinfected out of existence, and it was doubtful if there was any portion of the globe which could not be made healthful unless it were the glacial regions, because of their extreme cold. There was no reason why, in the coming century, the world should not become so much wiser, and sanitary science so greatly improve, that malarial fevers should, with the sums now spent upon armies and navies, be wiped from the earth.

Dr. T. Mitchell Prudden being requested to open the discussion, said he thought any reader of medical literature must have been convinced of the need of a better nomenclature of the contagious and infectious diseases. The matter, however, seemed to be beset with peculiar

difficulties. The original terms were not very clear, and they had been used in a great variety of senses. In fact, the growing knowledge of to-day would require that they either be discarded or be given a different meaning. It was the old task of putting new wine into old bottles. He thought it would be wiser to start with a rather simple classification. An understanding might be reached with regard to what were infectious diseases, and these might be divided into communicable and non-communicable, and this would serve as a basis to start on.

Dr. Brannan thought that if we could spread abroad a clear idea of the words contagious and communicable as applied to the infectious diseases, it would, perhaps, be all we could expect to do at present. He would agree with Dr. Thomson in calling all these diseases infectious, and in dividing them into communicable and non-communicable, but he might not agree with him in some other regards. For instance, there might be a difference of opinion as to whether diphtheria was a contagious disease, and yellow fever non-communicable, as claimed by Dr. Thomson. He would retain the word contagious for such communicable diseases as scarlet fever, measles, etc.

Dr. J. West Roosevelt thought the object which we wished to accomplish did not permit of hair-splitting refinements. It was not so important whether diphtheria was directly contagious or not, so long as the profession and the people were given to understand that a case in the neighborhood was liable, like a case of scarlet fever, to give rise to cases. Use terms, if possible, which the people could not fail to understand. There were other diseases which were not immediately dangerous, like typhoid fever and tuberculosis, and to them a term should be applied which, while denoting their danger, yet would distinguish between the mode of their transmission and that of contagious diseases like measles.

Dr. Armstrong thought the classification suggested by Dr. Thomson was one of the best he had heard, and he hoped the paper and the discussion would excite interest and lead to some practical result.

Dr. Alexander Hadden impressed the fact that the public, which had to give so much time to making a living, could not be expected to learn all the finer distinctions of medical terms, when the other various departments of science and learning were each claiming somewhat of their attention. Doubtless, the public schools would be the best source of spreading a knowledge of what the profession would have the public know, and we would do well if a clear understanding were given of the fact that, among the infectious diseases some were spread by direct contact, were contagious, while others were spread through the soil, by the food, etc.; and that all could be prevented.

Dr. Thomson closed the discussion, after which, on motion of Dr. Prudden, the President was empowered to appoint a committee of five to consider the nomenclature and classification of infectious diseases.

SECTION ON GENERAL MEDICINE.

Stated Meeting, March 20, 1894.

Charles E. Quimby, M.D., in the Chair.

Dietetic and Therapeutic Management of Typhoid Fever.—Dr. Adolph Zeh read a brief paper in opening the discussion upon this subject. The patient should be placed in a large, light, well-ventilated room, preferably at the rear end of the house, beyond noise, the bedding should be firm and soft, the covering only sufficient for comfort; if there were two beds it would permit of daily change. The patient should be kept absolutely quiet; use the bedpan to relieve the rectum and bladder. The body should be sponged with water and alcohol daily, only part of the surface being exposed at a time. Forestall bedsores, by washing skin exposed to pressure by suitable solution containing alcohol. Quiet should be maintained for seven days after subsidence of fever.

If the patient were seen early, give a single dose of ten grains of calomel, and after an evacuation give a dose of sulphate of magnesia, which removed deleterious intestinal contents, stimulated secretion, and aided the digestive functions.

Seek to keep the typhoid ulcers in an aseptic condition, which, however, could only be done indirectly. Avoid introduction of deleterious foods and resort to such treatment as would call forth active normal secretion of the various juices as they were secreted in health. To accomplish this one might give dilute nitro-muriatic acid, with or without pepsin, and fel bovis inspissatum. Salol, creosote, and other agents had been resorted to for intestinal antisepsis by some, but the author could not especially recommend them. For delirium apply cold to the head. In intestinal hemorrhage, observe absolute rest; ice-bag over the abdomen, injection of ergot and morphine. He had not seen perforation in private practice, but if it should occur he would call an experienced laparotomist to consider the expediency of opening the abdomen.

Among symptoms, hyperpyrexia had received most treatment, and the author hoped to hear a full discussion upon it to day. In his private practice, if the temperature remained high and the skin was dry, the patient restless, he would diligently apply sponging with tepid water to which alcohol had been added, and the ice-bag to the head. Only where the patient suffered from excessive bodily heat would he resort to the cold bath. A tepid bath cooled down would probably answer.

In reply to the question whether stimulants should be used, he would answer in the affirmative, for the disease was a prolonged and exhausting one, and collapse might occur between visits. No alcoholics at first; later, wine in the form of the liquid beef peptonoids; in severe cases whiskey early. Among other stimulants under special circumstances he mentioned caffein, camphor, ether, alcohol.

Food.—Boiled milk, one or two quarts a day, liquid beef extracts or solid extracts of beef, broths, and eggs beaten up in beef-tea. By the fifth day after the normal evening temperature he allowed scraped beef.

An Encouraging Disease.—Dr. W. H. Thomson had found typhoid fever, so far as treatment was concerned, an encouraging disease. It being an affection which ran a much longer course than such acute diseases as pneumonia, the physician had much wider opportunity for the exercise of his art. After an experience of thirty years he had come to have scarcely any apprehension when called to treat a case of typhoid fever, whereas in the case of pneumonia he believed that the treatment of to day was no more successful than that of the past generation. Typhoid was a chronic fever, presenting a succession of conditions which were extremely manageable. After referring to statistics in his service at Roosevelt Hospital, where he said the mortality from typhoid fever, exclusive of cases dying within four or five days after admission, was extremely low (between two and three per cent.), Dr. Thomson referred to treatment, and said the principal indication, he thought, was to prevent starvation. It had been shown by Fenwick that the peptic power of the stomach in this disease was lower than in almost any other, unless it were cancer. The digestive power of the stomach being no greater than that of the newly born infant, milk fed these patients should be diluted as much as that for a babe a week old. As a routine practice it should be diluted at least one-half with lime water, the diluent rendering it less likely to curdle in large flakes, and also acting as an antiseptic. Eighty grains of pepsin in the twenty-four hours. First, however, every case on admission was given ten grains of calomel and thirty grains of compound jalap powder. He would give this even if there were diarrhœa, for it was the best means for checking the diarrhœa. Along with the pepsin he gave bismuth, ten grains every three hours, its object being to prevent fermentation and tympanites.

When the tongue became dry, and notably when it showed tremor, an indication of advanced intestinal ul-

ceration, he gave turpentine in emulsion. Seldom were any other drugs called for than those mentioned.

Temperature. — As soon as the temperature rose above 103° F., the nurse had instructions to use cold as an antipyretic, but not in the form of the cold bath. Having for years used the cold bath, eight years ago he abandoned it for cold affusion. A rubber sheet was placed on the bed, the patient, lying in the middle of it, was sponged with water at the ordinary temperature, then with ice-water. then a large sponge was used, soaked with water, producing a sort of affusion upon the body, which was continued until the temperature began to fall. Never after it had fallen to 101° F.

As to the effects of this treatment, not one patient in forty had typhoid diarrhœa, not one in thirty had any delirium, the nutrition of the patient was maintained very well. He regarded delirium of typhoid fever as largely toxic, which was obviated by the treatment mentioned.

Regarding hemorrhage: during his last service at Roosevelt this has happened in nine cases and all recovered. In its treatment he condemned the cold coil, as he believed its tendency was to drive the blood internally and enhance the hemorrhage. He gave nitrate of silver and opium—a quarter of a grain of each—nine grains of resin of turpentine, with sufficient amount of liquor potassa added to be sure the turpentine would be rendered soluble. More than half the deaths at the hospital had been from perforation.

Dr. Thomson protested against the use of undiluted milk, as it produced flatulence, diarrhœa, and favored ulceration. He also strongly condemned the coal tar series of antipyretics because of their injurious effect upon the muscular function. It was as muscular paralyzers that they reduced temperature, whereas cold acted as a tonic when properly used. Cold made the breathing deeper, caused the patient to sleep, increased the secretions. It should be followed by friction. Pneumonia would not deter him from the use of cold, for when this complication arose it was usually due to cardiac debility, for which the tonic effect of cold was indicated.

Regarding cardiac stimulants he had relied on alcohol, but objected to its use in frequent and small doses. Stimulation never gave strength, and should be resorted to only to prevent cardiac failure for the time being, and for that purpose should be given in some amount. When he heard but one heart-sound, and that plainest at the base, he ordered stimulants until he could hear a clear first sound at the apex. Heart failure was most liable after midnight, hence half an ounce of whiskey every two hours until morning would be more likely to prove beneficial than at other hours, except where special indications arose. A dicrotic pulse sometimes indicated strychnia and citrate of caffein, given in combination with camphor, and considerable subsultus led him to substitute compound spirits of ether for whiskey.

Dr. Thomson knew of no treatment which would prevent relapses in typhoid fever. He knew of no disease in which the patient so often owed his life to the physician and nurse.

The Starvation Method.—Dr. Lesser had formerly employed the milk diet in typhoid fever. One patient refused it and he gave her only water, and she was able to live on that alone for twenty-one days. From that time he had begun to investigate how much or how little food typhoid patients required. While he did not recommend the method, yet he had treated eight cases since that time, giving no food for fourteen days, or until the patient actually desired something, and he then began to give diluted milk. He had not found alcohol necessary, but overcame cardiac weakness by caffein, etc. As to acids or alkalies, if the tongue were red he gave an acid, if coated gray or brown, he gave an alkali, as lime-water.

Dr. Max Einhorn thought too much stress had been laid on weakness of the stomach in typhoid fever. In an examination of the stomach contents in a few cases he had found the ferments and hydrochloric acid present, though perhaps not in as large quantity as in health. To say, therefore, that the peptic glands scarcely acted at all was going too far. Even if the secretions in the stomach were absent for a time, it did not follow that food could not be converted, for there were conditions in which the stomach did not secrete any juices at all, yet the patients lived healthily for years. It showed that the digestive power of the small intestine was sufficient to do the whole work, and in typhoid much of the tract was free from ulcers. While it was well to dilute milk, yet some physicians gave it pure and obtained very good results. Irritating substances should be avoided. He would not approve of the starvation plan, for during the time food was not taken the body must be consuming itself. He would also recommend alcohol as a fuel as well as a stimulant.

Dr. Zeh closed the discussion. In hemorrhage he would apply the ice bag over the ileo cæcal region, expecting that it would check, not increase, the hemorrhage. He thought it wrong to test the powers of the patient by withholding food

New Apparatus for Administration of the Brand Bath.—Dr. A. R. Bellamy sent a paper relating to the method of administering the Brand bath in typhoid fever, and a new apparatus, which consisted of a galvanized bath-tub on a frame, with rollers and crank for raising or lowering the mattress in the tub on which the patient was placed. With it one person could give the bath. The Chairman, Dr. Quimby, recommended the apparatus very highly.

THE NEW YORK PATHOLOGICAL SOCIETY.

Anniversary Meeting, January 10, 1894.

H. P. Loomis, M D., President.

A Staining Method.—Dr. J. M. Byron described an improved method of staining, which he said was based on the action of aniline colors on the protoplasm and the histone of cells. The fluid consisted of equal parts of Ehrlich's acid hæmatoxylin, a saturated solution of orange, and a saturated solution of rubin S., or, as it was more commonly called, acid fuchsin. The specimen, after being taken out of any solution, no matter what, was immersed in this staining liquid for a few minutes—the exact time must be determined by experience. After the sections had been deeply stained they were transferred to a decolorizing solution consisting of one part of an alcoholic solution of picric acid and two parts of distilled water. After a few seconds, the sections were transferred to absolute alcohol, then to the clearing agent (any of the essential oils usually employed), and finally into balsam. The method was not new in principle, but it seemed to possess more than the usual selective action on protoplasm and on different kinds of cells. Connective tissue was stained by it a permanent and very bright red. It was useful in distinguishing between a spindle-cell sarcoma and a myoma, for the cells of the muscular tissue were stained a dark yellow, the connective tissue red, and the spindle cells of sarcoma of a brownish tinge with blue nuclei. The stain appeared to be permanent.

Cardiac Dilatation; Pulmonary Thrombosis.—Dr. George P. Biggs presented a heart showing great dilatation and very little hypertrophy; the wall of the left ventricle appeared much thinner than normal, the valves were all normal, and their orifices were of normal size except the tricuspid, which readily admitted four fingers. The right lung was also presented, as it contained three large infarctions, the largest of which had the diameter of 7 ctm., and was located in the upper part of the lower lobe. The two others were about the size of walnuts and were situated a little lower. There were no infarctions in the upper lobe. There was one infarction in the lower and posterior part of the lower lobe of the opposite lung which measured 5 ctm. in diameter. The vessels leading to these infarcted areas

were occluded by what appeared to be thrombi, and all of these thrombi were whitish or grayish, and were firmly adherent to the vessel-wall, and were not broken down.

The specimens were removed from a man, forty years of age, a patient at the New York Hospital. He stated that two weeks before his admission he first noticed swelling of his legs, and that it was brought on by exposure to cold. Five days later he noticed, for the first time, blood expectoration, with marked dyspnœa, headache, and some thoracic pain. His principal complaint was the cough and severe dyspnœa. On admission he had a temperature of 101° F.; respirations were 38, and pulse 124. He was quite cyanotic and had slight general anasarca, and over the right chest posteriorly, in the lower part, was marked dulness, with broncho-vesicular breathing and voice, and many fine, moist râles. Over the lower part of the left lobe were numerous fine, moist râles. Fluid was also discovered in the right pleural cavity. The cardiac area seemed to be increased, and the apex-beat was most distinct three and a half inches to the left of the median line in the fifth space. The heart sounds were feeble, but there were no murmurs. The temperature continued to be elevated, all the symptoms increased in severity, and he died three days after admission. At the autopsy, in addition to the lesions already presented, there was marked chronic congestion of the kidneys and spleen, the heart was much distended with post mortem clots—some of them thoroughly decolorized, but none antemortem. All the cavities were enormously dilated with blood; the pulmonary artery was free from thrombi, and the aorta appeared to be in an unusually healthy condition. One branch of the coronary artery contained a spot of atheroma, but was otherwise normal. A careful examination was made of the venæ cavæ and the iliacs, but no thrombi were found. It appeared to be a case of primary pulmonary thrombosis at several points, producing the infarctions mentioned. The right pleural cavity contained 1,800 c.c. of sero fibrinous fluid, and there was considerable fibrine on the surface of the pleura posteriorly. There were some recent adhesions, and some older adhesions posteriorly. A teased specimen of the heart muscle showed under the microscope considerable granular and fatty change in the muscular fibre. This seemed to be the only explanation of the great dilatation. At the autopsy the question arose as to whether the pleurisy antedated the thrombi, and as to the relation of the cardiac dilatation to the condition present. It seemed to the speaker that the cardiac dilatation had existed for some time, as indicated by the change in the spleen and kidneys. At the time of the swelling of the limbs the patient probably contracted a subacute pleuritis which caused no symptoms until shortly before his admission, and it was probable that at about the same time the thrombi formed which resulted in the infarctions. There seemed to be no lesions of the vessels; hence it was due probably to the enfeebled circulation. The patient was not an obese individual. His occupation was not known.

Dr. Byron said that from the history and the pathological changes in the lung he would be inclined to think there had been an acute dilatation of the heart. It was a disease not often found in this country, but more common in countries where young military recruits were required to make forced marches. There seemed to him also to be more than a simple infarction of the lung; he thought there was some pneumonia. From the high temperature and the post mortem appearances it would seem that there was a multiple pneumonia besides the infarctions. If there had been no inflammation around the vein he could not understand how these multiple thrombi could originate.

Dr. Biggs said that when quite fresh the appearance of the specimen was not so much like that of pneumonia. The temperature during the man's last illness was only 100° to 101.5° F. In one other case, seen recently, in at least six points there were small thrombi which did not occlude the whole vessel. He saw no reason why they should not form as well in the lung as in the heart, where they were well known to be the result of a weakened circulation. The explanation given of the dilatation of the heart seemed to him quite plausible.

Dr. Le Boutillier asked if the veins of the legs had been examined, for a portion of a thrombus might have been detached from here.

Dr. Biggs replied that he had examined along the iliacs and down to the femorals, and had felt along these vessels.

Dr. T. M. Prudden said that one of the most interesting and obscure of the pathological lesions met with rather rarely was thrombosis of the pulmonary vessels. He had seen several such cases, and in none of them had there appeared to be a lesion of the vessel wall which would account for the formation of the thrombus, yet unquestionably such a lesion was present. The thrombi had been usually single, although he had met with multiple thrombi in two or three instances. The condition of the heart in this case would, it seemed to him, account for the thrombosis. The whole subject of pulmonary thrombosis required thorough study. In a considerable proportion of the cases he had seen the thrombosis had occurred after a safe and uneventful delivery.

On motion, Dr. Biggs was requested to report the results of his further study of the specimen.

Extreme Pulmonary Emphysema.—Dr. H. S. Stearns presented a specimen of extreme emphysema of the right lung. When the sternum was removed at the autopsy the right lung bulged out several inches beyond the chest-wall, and also over to the left side. The left lung was firmly bound down to the chest wall posteriorly, and was thickly covered with new fibrous formation. It was impossible to separate the heart from the pericardium, the left lung and heart being bound down together to the chest-wall. The capsules of the spleen, liver, and both kidneys were greatly thickened.

The subject from whom this specimen was taken was a woman, about seventy years of age, an inmate of the almshouse, who was supposed to be an ordinary case of phthisis. A few days ago she fell and struck her head, and remained unconscious to the time of her death.

The President said that he saw the specimen when fresh, and he had never observed before such extreme emphysema. The sudden death could be explained by the heart being crippled by adhesions, and by the dilatation of its cavities.

A Caudal Appendage.—Dr. Halsted Myers presented a tail-like appendage, about an inch and a half long, which he had removed from a baby girl. The structure was of fibrous tissue and fat; there were few blood-vessels and no excess of nerve-tissue, judging from the lack of sensitiveness. The coccyx made a right angle with the sacrum, projecting to the right side. The tail was attached to the tip of the coccyx. The vagina was in the median plane of the body, but the rectum was about an inch and a half to the right of this, near the end of the coccyx, in a deep supernumerary transverse gluteal fold.

Dr. Byron said that this specimen reminded him of a remarkable case of the kind which he saw some years ago, in which a man had a caudal appendage about eleven inches long. It was a continuation of the coccyx. The case was published at the time, and attracted considerable attention from the fact that there was only one other similar case on record, one observed by Nélaton.

The Brain in General Paresis.—Dr. E. D. Fisher presented a brain from a case of general paresis. It was removed from a man, fifty six years of age, a machinist by occupation, who was admitted to the Ward's Island Hospital, February 9, 1893. There was a history of intemperance, but none of syphilis. He had the usual delusions of grandeur in regard to wealth, and exhibited marked tremor in the face and tongue and hands. He finally passed into a state of dementia, and died a few days ago. The progress of the disease was quite rapid, its duration being only six months. There was a fairly

well marked meningitis involving the pia, and adhesions of the dura and pia, especially over the frontal lobes, where calcareous deposits could be felt. There was not much pachymeningitis. The appearance of the brain would seem to indicate an encephalitis also. The pial inflammation was more marked on the base of the brain. The arteries were the seat of atheromatous changes. Nothing abnormal was observed in the ventricles, but no microscopical examination had yet been made. The specimen represented the early stage of general paresis, where there was a simple meningitis or meningo-encephalitis. In extreme cases there was considerable pachymeningitis and sometimes meningeal hemorrhage, thus explaining the epileptic and the paralytic seizures. The age of the patient was fifty-six years, and his intemperate habits would account for the atheroma. General paresis could be said to be the only mental disease where definite lesions were invariably found. Although there had been some symptoms of tabes, he did not expect to find on examination of the cord either the posterior or the lateral columns affected.

Dr. Ira Van Giesen said that tabes began in several different ways—sometimes in the spinal cord, sometimes in the roots. He did not think we could say that cases of general paresis behaved differently from uncomplicated tabes. It might be a disease of the cord itself, or outside of the cord, and the disease in the cord be secondary to it. It was rare to find a pure case of tabes which had passed into general paresis, or, on the other hand, a case of general paresis with well-defined symptoms or signs of locomotor ataxia.

Dr. Fisher said that in many of these cases where there was apparently exaggerated reflexes and ataxia, the post mortem changes were very slight. In the cases of locomotor ataxia he had seen he could not recall one which had ever passed into general paresis, although he was aware that such cases had been reported.

Guanin Gout in the Hog.—Dr. James Ewing presented a specimen of this kind which had been recently sent to the laboratory of the College of Physicians and Surgeons for examination. The condition was not infrequently mistaken for trichinosis. The deposits in the piece of ham exhibited by the speaker were of a light color, and instead of being spherical, as in trichinosis, radiated into the muscular fibres. In its composition guanin was a product of nitrogenous metabolism very similar to uric acid, but less highly oxidized. It was found in the tissues in combination with carbonic acid or some organic acid, for when treated with sulphuric acid it effervesced, which pure guanin did not do. The deposits in the ham did not crystallize in the same form as pure guanin, but this process was modified by its combination with a colloid, probably a degenerated form of muscular tissue. As the specimen in this instance had been cooked before being submitted to examination, no further investigation could be carried on. About four other cases had been reported. It was first noticed by Virchow in 1856; then another German reported one case in 1868, and in 1888 Dr. Walter Mendelson, of this Society, received for examination an entire ham which was affected in this way. His report of the case appeared in the August number of the *American Journal of the Medical Sciences* for 1888, and contained references to the literature of the subject.

A Deodorizing and Preservative Fluid.—Dr. Ewing also spoke of the manner in which this specimen had been preserved. It had been found that when a tissue was placed in a jar on cotton saturated with a forty per cent. solution of "formaline," or formic aldehyde, that decomposition was arrested and the odor destroyed.

Dr. George Biggs said that about one year ago the late Dr. Vought presented a similar specimen to one of the societies in this city. It was at first thought to be a specimen of trichinosis. In that case the nodules were not as large as those seen in the specimen just presented.

Carcinoma of the Duodenum Compressing the Common Bile-duct; Obstructive Jaundice; Rupture of Dilated Gall-ducts with Resultant Perinephritic Biliary Cyst.—Dr. J. S. Ely presented specimens from such a case. He recalled the fact that in 1889 he had presented to the Society a rather remarkable case of primary carcinoma of the common bile duct. The case was noteworthy in that the only carcinomatous deposit in the body was a small tumor, 11 × 9 mm., situated at the opening of the common bile-duct into the duodenum. Pressure on the bile duct had caused an obstructive jaundice for which Dr. Hartley undertook cholecystotomy. The patient died of secondary hemorrhage, and the autopsy gave an opportunity of seeing a carcinoma which had undoubtedly developed from the common bile-duct, and at such an early stage that no secondary tumors had formed which might thus have thrown some doubt upon the actual point of origin of the tumor. A search through the literature at that time yielded only seven cases of a similar nature; hence it was rather remarkable that he should be able now to show another case which was its almost exact counterpart.

The patient, M. P——, aged forty-one, a native of Ireland, and a varnisher by occupation, was admitted to Bellevue Hospital on September 15, 1893. It was said that his mother died of cancer. In June, 1893, while at work, he was suddenly taken sick with diarrhœa and vomiting of blood, about half a pint of blood being ejected. This vomiting was repeated the next day, but this time the vomitus was dark colored, "like bits of liver." He had also slight occasional pain over the liver during the first three days of his illness. In about a week he noticed that he was becoming jaundiced, and from that time it was constant, and steadily increased in intensity. He had lost about fifteen pounds in weight up to the time of his entrance to the hospital. The bowels moved regularly, but the stools were white and pasty. His appetite remained good. Itching of the skin, biliary coloration of the urine, and the depressed mental condition so frequently observed as concomitants of intense jaundice, were noticeable features of his case. On admission physical examination disclosed nothing but intense jaundice, uniform enlargement of the liver (its lower border being three inches below the free border of the ribs), dilatation of the gall-bladder, and some increase of splenic dulness. There was no fever. Little change took place in his general condition until December 25th, when he was again seized with vomiting, which on the 27th culminated in his vomiting a considerable quantity of thin blood, after which he was much prostrated. On the 28th clots of dark blood and fresh blood were vomited, and it then became necessary to infuse him. Notwithstanding this, he died the next day, of exhaustion.

At the autopsy, which was performed by Dr. Waring, House Physician of the First Medical Division, the liver was found to be much enlarged and deeply stained with bile. The gall-bladder and biliary ducts were greatly dilated—the gall-bladder to the size of a small orange, the common bile duct to a lumen of 1½ ctm. in diameter. The dilated bile-duct protruded into the lumen of the duodenum to a distance of about a centimetre in the form of a large papilla. Just below this, in the wall of the duodenum apparently, was a hard circumscribed mass about the size of a small pea, which completely closed the mouth of the bile-duct, and evidently formed the obstruction which gave rise to the jaundice. In removing the left kidney it was found to be enclosed in an irregular cavity containing about a pint of thin greenish liquid. On further dissection this cavity was found to extend upward behind the spleen and stomach, to the posterior portion of the left lateral ligament of the liver, the layers of which were separated, and the cavity was traced to the edge of the left lobe of the liver, where it was found to be continuous with the ruptured extremity of a dilated gall-duct. This sac lay entirely behind the peritoneum, and the surrounding tissue showed only a slight degree of inflammatory reaction. There was no peritonitis. The stomach in places was much congested; there was

no ulceration. The mucous membrane of the duodenum appeared normal. The pancreas was normal, and no dilatation of its duct was discoverable. The spleen was slightly enlarged and showed a moderate degree of chronic interstitial splenitis. The kidneys were of about normal size. The capsule of each was somewhat adherent, its surface was granular, the cortex thin, and the markings indistinct. The left kidney in addition contained a small cyst. The heart and lungs were normal. All the organs were deeply stained with bile-pigment. Microscopical examination of the small mass in the wall of the duodenum which caused the obstruction showed it to be scirrhous carcinoma. Small alveoli filled with irregularly shaped cells were found scattered through a dense fibrous stroma.

The case, then, was one of carcinoma at the mouth of the common bile-duct, with obstructive jaundice, great dilatation of the biliary passages, and consequent rupture of one or more of those on the surface of the liver, giving rise to a large peri-nephritic biliary cyst. The specimen presented consisted of a portion of the left lobe of the liver, the gall-ducts of which had been injected by Dr. Roosevelt with a blue mass. At a point on its edge representing the posterior edge of the left lobe, the layers of the lateral ligament could be seen separated, and the blue injection-mass emerging from a gall-duct through a rupture in its wall, and entering the cavity of the retro-peritoneal cyst, thus affording indisputable proof of the origin of the cyst from the rupture of a gall-duct.

The speaker said that as a result of a very hasty consultation of the literature of obstructive jaundice, he had been unable to find a record of any case of rupture of a gall-duct. Orth, however, mentioned rupture as a rare consequence of traumatism in extreme dilatation of the gall-ducts, and he stated that this accident was quickly followed by death as the result of acute peritonitis. From this it would be inferred that he was not acquainted with extra-peritoneal rupture, such as occurred in the case just reported.

Dr. George P. Biggs said that a specimen showing rupture of the bile-ducts had been presented to the Society about two years ago by Dr. Herman M. Biggs. The rupture had occurred in the left lobe of the liver, from excessive dilatation resulting from a gall-stone obstructing the common duct. The case occurred at the almshouse, and had been seen by him during life. There was a large tumor in the left side of the abdomen, from which large quantities of biliary fluid were removed by aspiration on two or three occasions. It was found that a cavity had been formed, the posterior wall being composed of matted coils of small intestine, and the anterior wall by the parietal peritoneum.

The speaker also called attention to a case of primary carcinoma of the papilla of the gall-bladder, very recently reported by Dr. R. F. Weir. He had made the autopsy on this case at the New York Hospital, and had found a small primary adeno-carcinoma which obstructed both the common and the pancreatic duct.

Dr. Ely said that at the time he searched the literature and found the seven cases, he excluded every case in which there was any secondary nodule anywhere else in the body, simply to rule out any possibility of error. He wished to emphasize the fact that the carcinoma did begin in the common bile-duct or in the gall-ducts. There were a good many cases where the gall ducts would seem to be the primary seat of the carcinoma, but the existence of other nodules of carcinoma made this rather doubtful. In this case, as well as in that of Dr. Biggs, the rupture occurred in the left lobe of the liver. In Wickham Legg's book on jaundice it was stated that in cases where there was such extreme dilatation of the gall-ducts as to lead to the formation of cysts on the liver, and even in less severe cases, he had noticed the greatest dilatation in the left lobe of the liver; but he was unable to explain it.

Carcinoma of the Clavicle.—Dr. W. B. Coley presented a specimen of this kind. It was taken from a woman who was in the New York Cancer Hospital last August. In 1886 she was operated upon at the hospital by Dr. Clement Cleveland, for a tumor diagnosticated as a cystic tumor of the breast. This was soon after the opening of the hospital, and apparently no microscopical examination had been made. She left the hospital in four weeks, but returned in one year with a tumor in the same locality, and also enlarged axillary glands. These were removed, and she remained free from the disease for three years. A year and a half ago she noticed a small swelling at the inner end of the right clavicle, which grew slowly. She was admitted to the Presbyterian Hospital with this, last July. There were no tumors elsewhere. She was supposed to have sarcoma of the clavicle, and was sent to the Cancer Hospital, to the speaker, to receive inoculations of the toxic principles of erysipelas. A few injections were given pending the report of the microscopical examination. As this showed the growth to be a typical carcinoma, and as she apparently had internal complications, the treatment was discontinued. The tumor had, however, been reduced seven-eighths of an inch in circumference. The autopsy showed the entire inner end of the clavicle occupied by this tumor, which apparently started in the central portion of the bone, and which was attached to the first rib. The upper lobe of the right lung was also involved, and the entire liver was filled with an enormous number of carcinomatous nodules. The case was exceedingly interesting, because carcinoma of the clavicle was rather rare, and also because the interval between the last operation and the recurrence was about three years.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, March 19, 1894.

Samuel B. W. McLeod, M.D., President, in the Chair.

The Tubercular Diathesis Controlled by Gold and Manganese in Combination.—Dr. J. Blake White read the paper. He first showed a hypodermic syringe with a double barrel, which he had found best for making the injections of the gold and manganese preparations. With it he had made over seventy injections in one person without the slightest irritation following.

This paper was supplementary to one which he had read before the Society about three years ago, upon gold and manganese in tuberculosis and allied affections. Since then he had received testimonials from many sources bearing upon the value of the method then described. Considering that the testimonials came from prominent sources without request, he thought they should have much weight.

The prevalent impression of the past, that tuberculosis was an incurable malady, still lingered, in spite of the fact that numerous cases of recovery with or without treatment had been put on record. The importance of an early diagnosis could not be too strongly urged, yet the early stage was not only often overlooked, but it was difficult to convince patients that they had the disease after evident symptoms were present, so that precious time was lost before the commencement of treatment.

A very good analysis of cases amenable to treatment had been made by his friend Dr. O. H. Merrill, with whom he also agreed that too much attention may have been paid the bacillus tuberculosis compared with that given physiological chemistry, in whose vast laboratory there was yet so much to be accounted for. If the valuable time spent in bacillus hunting could only be devoted to careful study of the blood of tuberculous subjects the practical results in treatment would greatly outweigh those attributable to a knowledge of the tubercle bacillus. The proper assimilation of elements introduced into the system was a chief factor in the successful management of cases of tuberculosis.

A knowledge of the influence of gold and manganese

upon the powers of nutrition was possessed by the ancients, ample proof of which existed in literature. Had the author's own experience not confirmed their reports of the benefit derived from these agents he would have considered them too wonderful to believe.

The gold and manganese were best used hypodermically, although they might be administered by the stomach. They led rapidly to increased action in the organs of nutrition and respiration, enhanced the appetite, corrected assimilation, accelerated respiration, so that amelioration of important symptoms soon became manifest. The remarkable effect of these remedies was also manifest in certain other abnormal conditions, particularly in malignant disease, for under their influence he had seen tumors of the breast, pronounced by competent authorities to be malignant, disappear and the cachectic appearance clear up. He would advise their trial before resorting to surgery. In chronic skin affections of a scaly nature, enlargements, and some other conditions, this combination of remedies would often prove remarkably efficacious when judiciously administered. It was not easy to explain their action, but the author thought the gold acted upon the lymphatic and glandular systems and promoted assimilation, so that soon there was a decided improvement in the general health. In certain cases of the tubercular diathesis it seemed to act almost as a specific. The combination of gold with bromide of arsenic, recommended by Wood, had proven satisfactory in certain cases of tuberculosis, particularly those of the type classed as scrofulosis. The indiscriminate use of the remedies was not to be recommended.

Dr. Fernandez having observed a druggist's name upon the samples passed around, inquired whether the formula was secret.

Dr. White replied that he had published the first formula in 1890 For hypodermic use each dose contained one-fiftieth of a grain of the double chloride of gold and manganese, carefully combined with glycerine as a solvent, which prevented decomposition of the gold. The later preparation, referred to in this paper, was prepared in about the same way, every ten drops containing $\frac{1}{100}$ of a grain of arseniate of strychnia, two or three drops of tincture of gelsemium, and about $\frac{1}{25}$ of a grain of chloride of gold and sodium, and the same amount of iodide of manganese. When used as an injection, from one to two or three drops of the mixture was added to five drops of a one per cent. solution of carbolic acid, and a sufficient quantity of distilled water. As some care was required in making the preparation, the druggist whose name appeared on the bottle had been requested to keep it on hand. He agreed with Dr. Thomas Mays that the strychnia was useful chiefly through its influence upon the nervous system, particularly the pulmonary and stomach supply. For injections into pulmonary cavities a longer needle was used. Some cavities had healed, or remained dormant under its influence until some other disease had ended life.

Recommends Gold and Manganese Strongly.—Dr. Octavius A. White said he had from the beginning of their use been a witness of gold, and gold and manganese, employed subcutaneously. Over forty years ago he was in the habit of using gold, which he regarded as a remarkable agent; but he could not say that he then achieved the results obtained by the combination introduced by Dr. J. B. White. He regarded the present combination as exceptional in its fortuitous results. He had not seen an instance in which it had not proven beneficial, although some of the cases had appeared to be beyond therapeutic aid. The disease phthisis had either been seemingly cured, or had improved to such a degree that the patients enjoyed a longer lease of life. He had watched the introduction of this remedy with the deepest interest because previous medication had been so inadequate to the seriousness of the disease. He had seen individual cases improve under other forms of treatment, but not commensurately with this. From the first dose startling effects were produced: the appetite, which was always deteriorated in tuberculosis, was quickened, the night-sweats were subdued, the patient began to rest in comfort, the relief was so prompt that he requested continuance of the remedy. Dr. White said his testimony was that of one who had passed the age of enthusiasm; it was offered as that of an impartial observer advanced in years.

Some further remarks were made by Drs. Kohns, Proben, Valentine, S. Brothers, Hunter, S. B. Allen, Hawke, the President, Von Donhoff, and the author.

Specialties and Specialism.—Dr. Charles B. Mëding read an entertaining paper upon this subject, giving the hearer the impression that he thought specialties were too numerous and specialists took up their particular branches too early, or before making themselves thoroughly acquainted with general medicine and becoming experienced in the several departments of practice. The constant tendency of specialism was to exclusively local treatment, and oversight of disease related to other regions of the body. Many specialties and many specialists owed their standing to the inability of ordinary practitioners to perform the simple duties of their calling. The extravagant development of any department would lead to its decline, a fact which we were witnessing in certain directions to-day.

Dr. Von Donhoff agreed with the author that the tendency of young men to take up specialties before having had practice in general medicine was to be deprecated. He respected specialists who, having entered upon general practice, found themselves compelled for want of time to limit themselves to certain lines of work which experience had taught them they were best fitted to do.

Specialists Immemorial.—Dr. R. H. Anderson said specialists had always existed. They were present among Hindoo medical men three hundred years before Christ. They would continue to be as long as the law of Darwin existed. Some men were more fit than others physically and mentally to do certain things. Dr. Anderson believed with previous speakers that every specialist should be a general practitioner in a sense. He should know his notes, as the musician should know his, but it was not necessary that a man should practise general medicine many years before becoming a specialist. Napoleon had found concentration and rapidity necessary for success in almost anything. It was so in medicine, whose domain was too large for any one man to keep well informed in all its departments. The specialist, therefore, was merely a supply for a demand. Medicine owed more to specialists than to general practitioners so far as original research was concerned.

Dr. J. Blake White agreed with some of the speakers, that some doctors took up a specialty too early. It had always seemed to him that specialists, in a sense, should always be such by necessity. One should begin as a general practitioner, and master, as far as he could, every branch of medicine, and then fall into some special line as his ability and opportunity permitted. It was scarcely possible for one to be expert in all departments of medicine, nor would the means of most practitioners permit of purchasing a complete outfit of instruments of precision in all specialties.

Dr. Valentine: "When I was Professor Pallen's assistant, in the heyday of his glory as a gynecologist, a lady came in, and addressing Dr. Pallen asked, 'Are you not Professor Pallen?' 'Yes.' 'Do you not make a specialty of diseases of the womb?' 'No. My assistant does. I am a specialist in diseases of the navel.'"

After some further discussion pathological specimens were called for.

Decidua Vera.—Dr. A. Reich presented two specimens, the first of which was a decidua vera in a case of abortion at the sixth week. The presence of an apoplectic spot was the probable explanation of the abortion.

Carcinoma of Rectum; Nephritis with Uræmia.—The second specimen presented by Dr. Reich was from a case in which artificial anus had been made for partial intestinal obstruction, diagnosed probable neoplasm of

the rectum. There was evidence of hydronephosis, and the patient died, after about twelve months, of uræmia, and at the autopsy the hydronephrosis was found to have been due to obstruction of the ureter by the carcinomatous mass spreading from the rectum.

Nasal Irrigator.—Dr. Perry exhibited Dr. Bermingham's nasal irrigator, consisting of a small glass vessel of suitable shape for pouring water into the nostril for cleansing purposes. This method was least likely of all to lead to middle-ear disease.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MR. GLADSTONE'S SPEECH IN AID OF THE ANDREW CLARK MEMORIAL—INTESTINAL SURGERY—CASES AT THE CLINICAL AND MEDICAL SOCIETIES—SPECIMENS AT THE PATHOLOGICAL SOCIETY—CHOLERA—ROYAL SOCIETY—OPIUM COMMISSION.

London, May 5, 1894.

The event of the week has been the appearance of Mr. Gladstone, on Thursday, at the Prince's Hall, to speak in support of the proposal to commemorate the life and work of the late Sir Andrew Clark by a block of new buildings at the London Hospital. The great statesman spoke sitting, and declared it would have been a grief to him had he failed to be present, and he took the opportunity of saying a word in favor of the profession, to which he acknowledged himself indebted. He said the other professions had had advantage of this in time, for while lawyers had occupied a large place in the public eye for four or five hundred years the medical profession had more recently won its way, but its influence would go on increasing. He was old enough to have noticed no little change in the members of the profession, and bore testimony to their increased capacity and their larger ability to deal with the difficult and sometimes insoluble problems with which they are confronted. He felt that in a physician something besides knowledge and skill was required, and that was devotion; a quality which Sir Andrew Clark possessed in an eminent degree, for he loved his profession with a chivalrous devotion, and while such men as he survived it could not be said that the age of chivalry had passed. Mr. Gladstone said it was not for him to venture to speak of Sir Andrew's scientific attainments, but in every profession something more than knowledge was required, and that was character, and he held that it was a high privilege, an honor, and a benefit to the young men coming into the medical profession to contemplate the character and the career of such a man as Sir Andrew Clark, who gave himself, not merely to the acquisition of knowledge, but to the application of that knowledge to the relief of human suffering; he was indeed a typical representative of all that is best in the medical profession. Mr. Gladstone then referred to the early life of Sir Andrew Clark, and said that all through he had found delight and recreation in the consideration of divine subjects; he then proceeded to express his sense of the benefits he had personally derived from Sir Andrew's care, and declared he had come to that meeting not only from sentiments of duty and respect, but of gratitude and personal affection. He dwelt on Sir Andrew's patience, his thoroughness, his complete absorption in a case as if that were the single subject of his thoughts, and in his own case the warm friendship and assiduous care with which he had been watched; for though Sir Andrew was a younger man he had attended him with more than paternal affection, and never more than in the last year of his life. It was, said Mr. Gladstone, the happy lot of my wife to recognize at an early date what was in Sir Andrew Clark, and well do I remember how she returned from her first visit to the London Hospital, now some thirty years ago, and told me about "that great Andrew Clark." In conclusion he hoped the result of the meeting would prove that Andrew Clark was not forgotten, but that his work would be commemorated and that the noble profession of which the advance had been so great, and in the future would probably be greater, would help to make the memorial worthy of the name it would always be glad to have recorded on its annals.

Of course after the great orator other speakers would be at a disadvantage and what they said possessed little interest, except inasmuch as they formally moved and seconded resolutions to raise a sufficient sum of money to carry out the purpose in hand. No doubt the money will be raised, and the London Hospital obtain its new buildings.

Interstitial surgery is again to the fore. On Monday last at the Medical Society a case was related in which, on operation, three ruptures of the small intestine and laceration of the mesentery were found. The man had been kicked by a horse. Resection was performed and the patient did well for a time, but peritonitis occurred from the sutures giving way, probably in consequence of the bruised tissues in which they were placed, and perhaps, also, to the interference of the blood-supply through the injury to the mesentery. Another case was mentioned in which laceration of the mesentery was followed by gangrene of the intestine.

A case was then related of obstruction relieved by an opening into the cæcum; the patient did well but begged something further might be done to relieve him from the inconvenience of the discharge. The abdomen was opened, a tight fibrous stricture being found in the descending colon; it was excised and the ends joined; the man did well and the opening into the cæcum was closed. Subsequently he rode from Southampton to London on his bicycle, but a month or two later symptoms returned. Later another operation was performed, when nodular masses were found in the peritoneum and intestines, and so the wound was closed. At his death, some two months later, the resected part was found in a perfect condition, death having occurred from secondary deposits.

At the Clinical Society a case was related due to disease of the appendix in a man aged thirty-five. At the operation the appendix was removed and adhesions cut and torn through until the contents of the small intestine could be squeezed into the large. The patient was in a collapsed state for about thirty hours, but he rallied and recovery was uninterrupted. The collapsed condition was considered to be due to absorption of septic material. Another case was related of acute obstruction in which on making an opening in the middle line a small quantity of turbid serum escaped. Vascular adhesions prevented a systematic search for the source of obstruction and the patient became so profoundly collapsed that the wound was hastily stitched up. The next day it was opened in the central part, a small incision made into a prominent coil of small intestine and a cannula of a suction trocar introduced to which was attached a long India rubber tube leading to a vessel under the bed. The cannula was held in position for four hours and a half by relays of dressers, and a large quantity of the contents of the bowel came away. The patient made an excellent recovery and has had no trouble since his discharge last November. It was remarked by one of the speakers that it is curious obstruction should be so rare from appendicitis, considering how common disease of the appendix is. He mentioned a case of a man, aged thirty, who had passed through fifteen attacks, with the formation of a swelling the size of an orange, which disappeared with the discharge of pus by the bowels. When operated on the caput cæcum coli was found of an hour-glass shape, the appendix being reduced to a mere thread adherent along the cæcum; the adhesions were separated, and the wound closed, the patient recovering and remaining free from further attacks.

There was an interesting exhibition of specimens at the Pathological Society on the 1st inst., including one of

extreme tuberculous ulceration of the large intestine; another of cancer of the neck, the thyroid gland being involved and the trachea and œsophagus encircled by dense contracting tissue rendering both tracheotomy and gastrostomy necessary. There was some difference of opinion as to the origin of the growth. There was also rather a rare specimen of congenital hernia of the diaphragm, there being no deficiency but a pouch involving the left half without muscular fibres. The child had survived forty-three hours.

You will no doubt have received as full information as we have respecting the outbreak of cholera in Lisbon, so I need only say our sanitary authorities are on the alert, and we are not cherishing any serious apprehension of an invasion.

The Royal Society gave a conversazione on the 2d inst. There was a brilliant assemblage and some most interesting exhibits, one of them showing the influence of sunlight on bacteria, another illustrating the phenomena of chemiotaxis. There was also a model of a new Atlantic cable, through which it is expected that a speed of fifty words a minute will be attained and through which I may have the pleasure of saluting you.

A Blue Book is being issued containing the evidence of thirty-nine witnesses examined by the Opium Commission before it proceeded to India. Other parts of the Commission's report will follow.

THE CURE OF LOCOMOTOR ATAXIA.

To the Editor of the Medical Record.

Sir: It seems to me not less than a duty to say a word about the "case of Locomotor Ataxia cured," reported by Dr. T. E. Schumpert, in the Medical Record, of May 19th, for I fear some injury may be done by those who unguardedly accept the statements made.

There is no drug that is perhaps more universally discarded in the treatment of locomotor ataxia than strychnine. Ataxics are particularly sensitive to it, and I have seen a patient stiffened by $\frac{1}{100}$ of a grain. No drug will more surely give discomfort and pain. No doubt, in small doses carefully given, it sometimes has good symptomatic effects; but to give large doses, I am sure would be disastrous.

As for Dr. Schumpert's case, there is no evidence from his carelessly related history that the disease was locomotor ataxia, and as a matter of fact there is little doubt that it was one of neuritis, which would have got well under treatment.

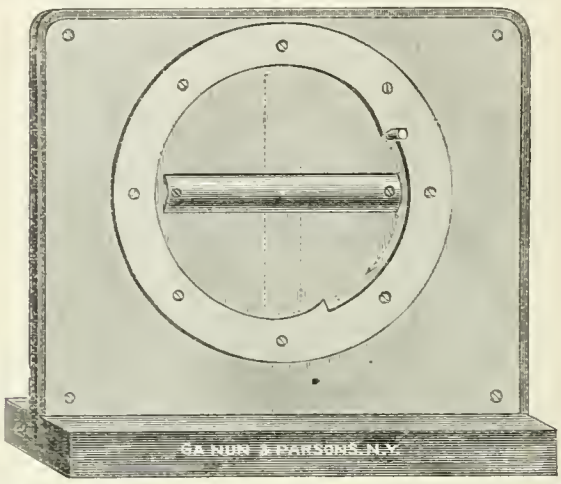
C. L. Dana, M.D.

50 West Forty-sixth Street, May 22, 1894.

The Therapeutic Value of Minor Gynecological Operations.—"For these reasons," says Dr. Goodell, referring to some operative failures in his experience, "I must confess to becoming far less inclined than formerly to operate on trifling lesions of the reproductive organs, and especially on small tears of the perineum, the repair of which is painful, unnerving, and generally of doubtful expediency. I have become very sceptical of the influence of such lesions upon the general health, and have come to the belief that, even in bad cases, it is greatly overrated. In my experience the mistake usually made in these cases is that of attributing to the lacerations the mock uterine symptoms of nerve prostration. About this there can be no error, for I have over and over again, without any surgical treatment whatever, cured of all their ailments patients who had been sent to me for the very purpose of undergoing some operation on the womb, on the perineum, or even on the ovaries themselves."

Epistaxis.—Hutchinson places patients with obstinate nose-bleed in the sitting posture and with the feet in a deep pail of water as hot as can be borne. He says this never fails to arrest the hemorrhage.

New Instruments.



AN ADAPTATION OF THE MADDOX CYLINDER FOR USE ON THE PHOROMETER.

By JUSTIN L. BARNES, B.S., M.D.,
NEW YORK.
ADJUNCT PROFESSOR OF OTOLOGY, UNIVERSITY MEDICAL COLLEGE; ASSISTANT SURGEON, MANHATTAN EYE AND EAR HOSPITAL; FELLOW NEW YORK ACADEMY OF MEDICINE, ETC.

The accompanying cut shows the construction of an adaptation of the Maddox cylinder for use on the phorometer.

It consists simply of a carrier, like those supporting the usual phorometric prisms, in the upright of which is carried a mechanism by means of which the cylinder may be rotated into exact vertical or horizontal positions, a pin and stop being so contrived that these points are secured with precision, leaving nothing to the fallibility of the personal equation in making these adjustments.

The cylinder, being an infinite number of prisms

with their bases in apposition with the cylindric axis, produces in the eye which views a distant light through its medium, a juxtaposing multiduplication of the flame, which therefore appears as a line of light.

When the cylinder is turned into the vertical position this line is necessarily horizontal, and conversely; by means of which vertical and lateral heterophoria are determined much after the manner in which, with enlarged copies of the "Graefe dot and line" placed at twenty feet, I have, for confirmation, for years often diagnosed and measured these insufficiencies.

Now, with this appliance placed before one eye (and for convenience of reasoning I always select the same eye, usually the right), this line, in orthophoria, with the cylinder in any position, exactly intersects the single flame seen by the other eye, both eyes being, of course, open simultaneously; while in heterophoria this line does not cross the single light, but is found to be more or less remote.

The quality and quantity of heterophoric aberration are diagnosed and measured in the usual fashion and no extended discussion is pertinent in this connection.

When the cylinder is vertically placed over the right eye, if the single flame is above the line the fault is right hyperphoria, and conversely.

When the cylinder is in the horizontal position over the right eye, and the flame is to the left of the resulting vertical flame line, the conditions present are those of homonymous lateral diplopia with esophoria; when contrariwise, there is discovered to be crossed diplopia with exophoria. The prisms which produce coincidence of flame and line by intersection are the measure of the muscular errors.

This instrument, which further adds to the list of means of precision, can be had of Messrs. Ga Nun & Parsons, of New York, who kindly constructed it at my suggestion.

3 East Forty-first Street.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 19, 1894.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	4	3
Scarlet fever	111	12
Cerebro-spinal meningitis	3	6
Measles	180	7
Diphtheria	244	71
Small-pox	10	5
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

The Great Medical Error.—In the treatment of the diseases of women, at the present time, there seems to me to be a tendency to lay too much stress upon lesions of the reproductive organs. Too little heed is, therefore, given to the nerve element of woman's diseases, and as a natural sequence the surgical feelers and antennæ of the medical profession, always too keenly sensitive, vibrate vehemently at the approach of an ailing woman. This trend of the profession, to appeal to the knife as the great panacea for woman's diseases, is seen everywhere. It prevails alike in city, town, village, and hamlet. It asserts itself in every medical discussion and stands out in bold relief upon the pages of every medical journal. It has caused many needless sexual mutilations and unnecessary operations, and it is, in my opinion, the great medical error of the day.—*Goodell.*

The Canny Prince of Servia.—Dr. F. Semeleder, of Cordova, Mexico, writes: "An article in your issue of March 31st, entitled 'Skilled Labor and High Fees,' reminds me of an anecdote the late Professor Edward Jäger, of Vienna, related of his father (at that time the first oculist in Europe), and of Milosh Obrenovich, who then was the first Prince of Servia. Milosh had cataract of both eyes. Jäger operated for him on one eye and with good result. Milosh paid for this operation 6,000 ducats (nearly $10,000), a big fee in those times. When Jäger had operated on the second eye and the result was happy again, Milosh sent him this time 3,000 ducats. Later they met at the table of Prince Metternich and were seated one next to the other. Jäger asked his neighbor why he had only given him 3,000 ducats for the second operation. Milosh, with the cunning smile of a savage or a peasant, answered, 'If I had had a third eye to be operated on, I would no doubt have paid you again 6,000 ducats for the second operation.' May not his sublime Highness the Shah of Persia feel inclined to play a similar trick on Dr. Galezowsky?"

Report of the Pasteur Institute.—During the year 1893 the Pasteur Institute in Paris received for treatment 1,648 persons who had been bitten by rabid animals. Of these, four died, the others, as far as known, escaping hydrophobia.

Oranges and Alcohol.—It is asserted, upon whose authority we know not, that the craving for alcohol may be greatly diminished by the use of oranges eaten to the number of six or eight a day.

Monsieur Desprès is the object of much ridicule from his Parisian *confrères* because of his little faith in the value of antisepsis. One medical journal says that M. Tailhade, the anarchist poet, who was wounded by the explosion in the Café Foyot, cried out in alarm when told he was to be taken to the Charité, and begged that he be not allowed to fall into Desprès's hands. Another paper announces with black headlines that this surgeon was observed recently to pass a trocar through the flame of an alcohol lamp before tapping a hydrated cyst, and the onlookers telegraphed abroad that he had become a convert to antiseptic surgery. The wound suppurated, however, and now antisepsis is less in favor than ever before.

Death Following a Box on the Ears.—A German soldier was boxed on the ears several times by an officer for not being quick enough in obeying orders. He was soon after seized with headache, vertigo, and ringing in the ears, became comatose, and died within a few days. The autopsy showed cerebral hyperæmia with an effusion of blood in the pia mater.

Leprosy and Measles.—Dr. Impey, of Robben Island, writing in the *South African Medical Journal*, expresses the belief that leprosy will be cured, not by internal remedies or by external application, but by the introduction into the system of some bacillus inimical to the growth of the leprosy bacillus. This bacillus, he thinks, is to be found in measles.

Washing Underclothing in the Russian Army.—According to *Vratch* (No. 7, 1894), a small quantity of petroleum is added to the soap-suds in which the underclothing of Russian soldiers is boiled. The clothes are whiter, are less injured by washing, and a considerable saving is made in soap. The same process is to be employed in the German military hospitals.

Biehromate of Potassium in dyspepsia and gastric ulcer is recommended by Dr. Thomas R. Fraser. He gives it in doses of gr. $\frac{1}{10}$ or gr. $\frac{1}{12}$, twice or thrice daily.

The Degrees of Fertility at Different Age-periods in Men and Women.—Some interesting observations were communicated at the meeting of the Royal Society, on January 18th, in a paper by Joseph Koösi, member of the Hungarian Academy of Sciences. The subject was an inquiry into the fertility of each sex, based upon observations made with regard to statistics available at Buda-Pesth. Among husbands of thirty-nine years of age the probability of becoming fathers is, with a wife of twenty years, thirty-one per cent., and with a wife of thirty years, twenty per cent. On the other hand, for husbands of forty years the chances are, with a wife of thirty-five years, twenty-seven per cent.; with one of forty years, seventeen per cent.: and with one of forty-five, only two and a half per cent. Again, two degrees of fertility appear to exist for each age, namely, the physiological and the actual fertility. The former is the result of the unrestrained exercise of the sexual functions, while the latter is the outcome of such functions controlled by forethought initiated by motives of morality. It is among newly married couples, admits the author, that the physiological factor is nearly exclusively active. But after the birth of the first child the degree of physiological fertility declines, and under the influence of the moral factor it is reduced to an extent exceeding all expectation. For example, with mothers of thirty to thirty-five the reduction is to seventy-eight per cent.; with those of forty-three, to two per cent.: that is to say, ninety-eight per cent. of the physiological faculty is suppressed in these latter cases. With men the influence is also very great, though it is less pronounced than in women.—*Medical Press.*

The Earl of Carriek has Hæmorrhoids, or did have. He has written a letter to a patent medicine concern, stating that he was thus troubled, but that the great remedy "touched the spot" and relieved him. Lady Keane has also given a certificate to the effect that her piles were cured by the same remedy. Times are hard now, and the clergy will find a dangerous rival in the nobility in the once lucrative employment of composing patent medicine certificates.

The King of Italy is reported by a London paper to be suffering from cancer of the larynx, and will, it is said, soon submit to an operation in the hope of relief.

International Medical Congresses.—The following are the dates and places of meeting of the eleven congresses thus far held: 1867, Paris; 1869, Florence; 1872, Vienna; 1875, Brussels; 1877, Geneva; 1879, Amsterdam; 1881, London; 1884, Copenhagen; 1887, Washington: 1890, Berlin; 1894, Rome.

Attending Physicians in the Paris Hospitals.—There are 88 physicians, 44 surgeons, and 9 accoucheurs in the services of the various public hospitals of Paris. Attached to the Central Bureau are 18 physicians, 14 surgeons, and 4 accoucheurs. There are 16 consulting physicians and 9 consulting surgeons, making a total of 202.

Some Chinese Hints on Midwifery.—Dr. John G. Kerr, of Canton, China, has been translating the *Tai Shang Pin*, or Midwifery Made Easy. The work shows that the Chinese possessed many sensible ideas on this subject. Among the interesting paragraphs are these: When the child is born, it may not be able to cry, or it may be already dead. It should be quickly wrapped up in cloths, and the cord then burned off with perfumed oil-paper, which will cause the warmth to enter the stomach, and life will be manifested by the return of the voice. If the cord has already been cut, the child must die. . . . It is of the first importance in nourishing the womb to restrain the passions, and, if this cannot be done, to limit them. When lust is moderated, the heart is undisturbed, and the spirits of the womb are more quiet. When the womb is at rest it is more favorable for the nutrition of the child; it will be more easily delivered, and will be healthy and long-lived. In nourishing the womb it is best to be moderate in doing work. Look at the females in the country, the servants, and those of the lower orders. They suffer very little from diseases of the womb, because labor promotes the circulation of the blood and spirits, and gives strength to the bones and muscles. When the womb is accustomed to motion in the abdomen a slight fall will not be followed by an injury. If one lives in luxury and ease the bones and muscles are weak and delicate, and the circulation is sluggish. Any acciden' to such persons is immediately followed by falling of the womb. . . . In the after-treatment the customs of different places are not the same. In one place they use red sugar, in another, *Shau Cha*, in another, *Ng Chaü-ü*, and in another, pepper boiled in water, but none of these is as good as the mixture of boy's urine and whiskey. For pain in the stomach, the infusion of *Shang Fu* is infallible.

The Axis-Traction Forceps and Antepartum Douche as causes of Rupture of the Perineum.—Dr. George M. Boyd, in an article on injuries to the pelvic floor, says: That the forceps is the cause of many tears I believe, and I find in the forty-two operations reported a confirmation of this. In my experience we have a new factor in the axis traction rods of the modern forceps, as a cause of these injuries. Let us be mindful that while we are making traction in the axis of the pelvic canal that we may be also producing, by pressure, serious damage to the pelvic floor. Is the use of the bichloride antepartum douche a cause—washing away the natural secretions and producing a dryness and rigidity of the soft parts, as it is claimed by some? If this is the case, then we have an explanation of many of the injuries I have reported, for in all cases where the first stage of labor was not completed before admission, the patient was given a 1–4000 antepartum douche. Should the discussion favor or oppose its use, because of this danger, even then I should feel compelled to use it as a prophylaxis against gonorrhœal ophthalmia and septic infection.

Neebe's Treatment of Sweating Feet by Crude Hydrochloric Acid.—When the feet are very tender, especially in hot weather, treatment is preceded by an eight to ten days' application of compound talc powder, which is sprinkled in the stockings. The application of the acid is best made in the evening. The crude hydrochloric acid is poured into a flat vessel of stone or glass or porcelain, sufficiently large to receive the two feet. Since the soles of the feet and the skin between the toes are the seat of the trouble, sufficient hydrochloric acid is poured in the vessel to completely cover the soles. It should not be allowed to come in contact with the skin of the back of the feet. The heel is kept in the acid for five minutes; then the sole of the foot for ten minutes. After this the feet, especially the skin between the toes, are washed in soap and warm water. Soaking in the acid must be at once stopped as soon as pain is excited, and the painful spots must be treated with zinc ointment until healing is complete. The process of soaking may be repeated twice weekly.

The International Congress.—The medical press throughout the world is almost unanimous in pronouncing the Rome Congress a failure. The object aimed at was evidently the glorification of Baccelli rather than the advance of science or the comfort of the members, as everyone present in Rome could not fail to observe from the many advertisements of this gentleman scattered broadcast throughout the length and breadth of the Eternal City.

The Favorite Beverages in England are tea, beer, and light wines, which are gradually taking the place of coffee, spirits, and heavy wine. The consumption of sherry and port has decreased in the last seventeen years from 11,000,000 gallons per year to 4,700,000, while tea shows an increase of 6,000,000 pounds during the same period, and light wines of nearly 2,000,000 gallons.

BOOKS RECEIVED.

Diseases of Women. By Henry J. Garrigues, M.D. 8vo. 690 pages, illustrated. Cloth, $4; Sheep, $5 net. W. B. Saunders, Philadelphia, Pa.

An American Text-Book of the Diseases of Children. Edited by Louis Starr, M.D., assisted by Thomas S. Westcott, M.D. 8vo, 1190 pages, illustrated. Cloth, $7; Sheep, $8; and half Mo., $9. W. B. Saunders, Philadelphia, Pa.

Minor Surgery and Bandaging. By Christopher Heath, F.R.C.S. Tenth Edition. 12mo. 389 pages, illustrated. P. Blakiston, Son & Co., Philadelphia, Pa. Price, $2.00.

A Text-book of Gynecology. By James C. Wood, A.M., M.D. 8vo. 858 pages, illustrated. Boericke & Tafel, New York.

Pain, Pleasure, and Æsthetics. By Henry Rutgers Marshall. 8vo. 359 pages. Macmillan & Co., New York. Price, $3.00.

Clinical Lectures on Pediatrics. By A. Jacobi, M.D. 8vo, 195 pages. Bailey & Fairchild, New York.

Lectures on Auto intoxication in Disease, or Self-poisoning of the Individual. By Charles Bouchard. Translated by Dr. Thomas Oliver. 8vo, 302 pages The F. A. Davis Co., Philadelphia, Pa. Price, $1.75.

Tumors, Innocent and Malignant. By J. Bland Sutton. 8vo, 511 pages, illustrated. Lea Brothers & Co., Philadelphia, Pa.

A Practical Treatise on Medical Diagnosis. By Dr. John H. Musser. 8vo, 881 pages, illustrated. Lea Brothers & Co., Philadelphia, Pa.

The Year-book of Treatment for 1894. By Barclay J. Baron, et al. 12mo, 492 pages. Lea Brothers, Philadelphia, Pa.

A Manual of General Histology. By William S. Gottheil, M.D. 12mo, 148 pages, illustrated. Sabiston, Murray & Co., New York City.

Congenital Affections of the Heart. By George Carpenter, M.D., Lond. 12mo, 103 pages, illustrated. John Bale & Sons, London, Eng.

Politzer's Text-book of the Diseases of the Ear and Adjacent Organs. Translated by Oscar Dodd, M.D. 8vo, 739 pages, illustrated. Lea Brothers & Co., Philadelphia, Pa.

Syphilis in the Innocent, Clinically and Historically Considered, with a Plan for the Legal Control of the Disease. By L. Duncan Bulkley, A.M., M.D. 8vo, 398 pages. Bailey & Fairchild, New York City.

Hospitals, Dispensaries, and Nursing. Edited by John S. Billings, M.D., and Henry M. Hurd, M.D. 8vo, 718 pages.

The Microscope and Microscopical Methods. By Simon Henry Gage. 8vo, 163 pages, illustrated. Comstock Publishing Co., Ithaca, N. Y.

The Dispensatory of the United States of America. By Dr. George B. Wood and Dr. Franklin Bache. 17th Edition. 8vo, 1930 pages. J. B. Lippincott Company, Philadelphia, Pa.

A NOMENCLATURE FOR THE DIFFERENT CLASSES OF INFECTIOUS DISEASES.[1]

BY W. H. THOMSON, M.D.,

NEW YORK.

PROFESSOR MATERIA MEDICA AND THERAPEUTICS, UNIVERSITY MEDICAL COLLEGE, NEW YORK.

MEDICAL terms become important as such in proportion to their influence upon conduct. When the effect of the wrong use of some such terms may needlessly disturb the affairs of a household and seriously alter the natural relations of its members to each other, or alarm an entire neighborhood, or empty a town, or greatly derange the commerce of a country, it certainly behooves the medical profession to endeavor to prevent all such misunderstandings by making the meaning of such terms as definite as possible. Instead, however, of this having been the case in the past, there is no more unpleasant feature in the history of medicine than the long confusion, often marked by angry controversy, which has characterized the use by medical men of the terms intended to be descriptive of the nature of infectious diseases.

How untoward in its results such confusion may be is well illustrated by the variety of ways in which the term "contagious" has exerted an influence for evil both on the profession and on the public. No word can escape entirely from association with its primary meaning, and particularly no descriptive name can wholly lose the original hue of its derivation. To spread by contagion means to spread by touch, and it is impossible thoroughly to dispossess anyone's mind, whether medical or non-medical, of certain suggestions connected with this first significance of the term. It was thus that this primary meaning of the word contagious generated the notion that a sort of continuity, like the spread of a fire among combustibles, was the essential element in all contagious diseases, and hence if any other diseases did not so spread, but could spring up separately without contact with previous cases, it was accordingly inferred that there could be no community between them and the contagious diseases. The term contagion, in fact, monopolized the mental conception entirely, to the exclusion of every other, with the result that when a particular epidemic disease was shown to spread in a community without personal contact with the sick, it was forthwith pronounced to be wholly different in kind from contagious diseases, and the public was exhorted to dismiss all fear of its having any relationship whatever to such diseases, and to act accordingly.

Asiatic cholera, for instance, was easily shown to be a non contagious disease, because in every epidemic of it, especially at the beginning, persons fell victims to it who were known not to have been near anyone sick with cholera, while those who themselves attended the sick, living, for example, on the banks of a stream, were not as often attacked as persons who lived at a distance down that stream. The next logical conclusion in this train of reasoning was that cholera had nothing to do with human intercourse any more than that ague has to do with human intercourse. This seems to have been the opinion of the Medical Society of Massachusetts, when, in the year 1855, it promulgated with much emphasis, for the benefit of the public, the doctrine that Asiatic cholera was in no sense contagious, but rather that it was a miasmatic disease dependent upon some general element suspended in the atmosphere.

Ere long, however, the close and unmistakable relationship of the spread of cholera to the routes of commerce or of travel obliged many to admit that this disease had something to do with human intercourse. But if so, such a fact was conclusive against its being a miasmatic disease, for miasmatic diseases never leave their localities nor go on journeys. Hence, as cholera was neither contagious nor miasmatic, it was proposed to call it "infectious." But this designation was equally unfortunate with contagious as a specifically descriptive term, though in an opposite fashion, for whereas "contagious" strictly limits the conception of the mode of extension, "infectious" defines nothing as to mode, for according to its original meaning it can be applied equally well to contagious, to purely miasmatic diseases, and also to the class which are neither miasmatic nor contagious, like typhoid fever and cholera. A man can be as truly infected with malaria by going to a malarious locality as he can become infected with small-pox by entering a room where a small-pox patient lies, and again, he can be likewise infected with typhoid fever and with cholera by going to a town where these diseases are epidemic. Therefore, to term cholera infectious only served to make the conception of its true nature more vague than ever.

Vague fear is the mother of panic, and vague terms are the most potent generators of vague fears. When medical men themselves are not sure how the different classes of epidemic diseases should be distinguished from each other by descriptive names, the public can scarcely know what to think about them, and hence is open to the occurrence of as needless a fright as that about cholera which cost the city of New York so much in the autumn of 1892.

This subject, moreover, has assumed of late quite a new phase and importance by the fact that the progress of medical knowledge has led us to add to the list of specific infectious diseases both tuberculosis and ague. But if the profession is to announce that pulmonary consumption is truly infectious, the public has every right to ask just what we mean by it. Is infectious the same thing as contagious; and if not contagious, then what is it? We cannot minimize the importance of this matter, for without more specific explanation it will be impossible to prevent painful results in conduct toward consumptives owing to the natural interpretation by ordinary persons of the term infectious as implying necessarily some form of contagion in this very general disease.

Moreover, it is to the immediate interest of the profession, as well as of the public, that the differences in the modes of infection between the various classes of infectious diseases should be clearly defined so as to prevent both disbelief in, and opposition to, our recommendations as a profession about them. One of the chief obstacles to the diminution of tuberculosis either by precautions taken with consumptive patients, or by the sacrifice of tuberculous cattle, will be the denial that consumption is an actively infectious disease, simply because common experience shows that it is by no means contagious. A general incredulity is already manifest in newspaper comments on this subject, which is based upon appeals to the infre-

[1] Read before the New York Academy of Medicine, May 3, 1894.

quency with which consumptive husbands or wives communicate the disease to their life partners. We even see communications signed by physicians taking the same ground on the same argument, with appeal to the Report of the Collective Investigation Committee of the British Medical Association of 1883, on this point, as disproving the communicability of consumption at all, and hence they inveigh against the inhumanity of the doctrine of the contagiousness of phthisis, thus plainly supposing that the terms infectious and contagious are interchangeable.

Meantime it cannot be said that on account of the insufficiency of our knowledge we as a profession are still unable so to distinguish the chief characteristics of infective diseases that we cannot classify them accordingly. On the contrary, in no respect has our advance of late years been so distinct and gratifying as in the discovery of just how infective diseases are infectious, and often to arrest their spread by specific knowledge on that very point. There has not been, for example, in all history such a striking illustration of the supreme advantage of definite scientific acquaintance with the mode of infection as in the case of the recent arrest, in the very act, so to speak, of Asiatic cholera at the great assemblage of pilgrims in its native habitat at the Kumbh Fair at Hardwâr in India. As a conclusive illustration of our contention we beg leave to cite the following extract about this case from a lecture delivered, February 14, 1894, by Dr. E Klein, F.R.S , before the London Institution.

Dr. Klein says: "A well known fact, which has received unfortunately a great many illustrations, is this, that pilgrims in India carry the contagium of cholera from the fairs or festivals to which the disease is brought from the endemic area to localities which were previously free from cholera" We may in passing note that even Dr. Klein speaks of the contagium of cholera, whereas cholera is in no proper sense a contagious disease. Need we wonder, then, that with medical authorities using such loose terms about infectious diseases ordinary people will dread the contagiousness of cholera, tuberculosis, and typhoid fever. "One such fair," he continues, "is particularly notorious, and it has in the past always been a source of the greatest anxiety to the Government of India. This is the great religious festival, or Kumbh fair of Hardwâr, a town on the Ganges, but situated outside the endemic area of cholera. This great Kumbh occurs once in twelve years, and it is attended by large numbers of pilgrims, a proportion of those coming from districts in which cholera is always endemic. It has thus frequently happened that this great concourse of pilgrims has been followed by a wide diffusion of the disease. The great Kumbh is principally a religious festival, and is looked upon by Hindoos as one of peculiar sanctity, and the very aim and object of the pilgrimage is to bathe in the sacred Ganges and to drink its holy waters. In 1891, when the last Kumbh fair was held, 800,000 to 1,000,000 pilgrims assembled at Hardwâr, and to get an approximate estimate of the enormous pollution to which the sacred Ganges is subjected on this occasion, and the great risk from cholera to which those who drink of its waters are exposed, I will mention what Dr. Simpson, the able health officer of Calcutta, states: In describing the scene at the 'sacred pool' at Hardwar, somewhat retired from the rest of the river, to bathe in which and to drink whose waters the pilgrims gather in such multitudes, Dr. Simpson states that as the bathing went on the clear stream became a muddy one, that from April 8th to April 12th there was always passing through the sacred waters 'a seething mass of humanity' in constant motion through the pool at the rate of four hundred to five hundred per minute. You can easily picture to yourselves that a few cases of cholera introduced into such a multitude would easily cause not only an outbreak of cholera there and then, but would, by the returning pilgrims, be carried far and wide. Thus a sanitary commissioner says of the Kumbh on previous occasions that very little remains on record, but that little is a record of disease and death. So grave was the outlook that the question of prohibiting the fair in April, 1891, was seriously discussed, and the official opinion of many government officials of great experience was that the most complete sanitary arrangements would be powerless to prevent the spread of cholera should the fair at Hardwâr be allowed to take place."

But in 1891, armed with the knowledge of just how cholera infects, and that without its being taken in food or drink cholera cannot travel six inches, the British sanitary authorities grappled with the problem by allowing the fair to be held, and then stamped out cholera every time it appeared in the midst of this Asiatic crowd, as effectually as a fire can be easily extinguished if taken just at its beginning.

Nor, with respect to other infective diseases besides cholera, is our knowledge less definite as to the ordinary modes by which they are propagated. We have now got rid utterly of that nightmare of a miasm, or deadly diffusible gas, which weighed upon the minds of medical men for so many generations whenever they thought of epidemic diseases, and enough is known for us now to tell the world both what infection means, and what the chief modes of infective propagation are, and hence, how to guard against them.

How readily this can be done I beg leave to illustrate by submitting the following classification of infectious diseases, for the consideration of the Academy, with the hope that it will serve to invite discussion on a subject of great public importance, namely, the adoption by the profession of a definite nomenclature descriptive of the various classes of infectious diseases.

This classification is as follows:

1. All infectious diseases are due to the presence of their specific living micro organisms in the body.

2. Infectious diseases are divisible into three classes—(1) the communicable; (2) the non-communicable, and (3) the septic.

3. The communicable diseases are those whose origin is from an animal body. Examples of which are small-pox, Asiatic cholera, and tuberculosis.

4. The non-communicable infectious diseases are those whose origin is not from an animal body, but from a place or thing. Examples of which are ague, yellow fever, and miasmatic diseases in general.

5. The communicable diseases are divisible into two classes, according to the ordinary modes of their communication.—(1) into the contagious, and (2) into the non contagious communicable diseases. The contagious communicable diseases are those in which simple proximity to the infected with them is sufficient to communicate the infection to those susceptible to them. Examples of which are, typhus fever, scarlet fever, small pox, measles, diphtheria, mumps, whooping-cough, etc. Isolation of the sick with them, therefore, is needful to prevent infection.

The non contagious communicable diseases are those in which the communication is not by simple proximity to the sick, but through intermediate means of communication. Isolation of the sick with them, therefore, is neither needful nor effective, in comparison with measures directed against the intermediate means of the infection. Examples of these diseases are—typhoid fever, Asiatic cholera, and tuberculosis.

6. The septic infectious diseases are those in which the infection has gained entrance through a wound, or damage, by inflammation or otherwise, of the skin or of a mucous membrane. Examples of these are surgical infection of wounds, erysipelas, hydrophobia, tetanus, etc.

Lastly, all infectious diseases can be prevented by measures of disinfection applicable to each.

This statement of infectious diseases and of their respective classes, if correct, would have the advantage in my opinion of being intelligible to the most ordinary readers on account of its being free from all technical terms. In the first place, it is desirable, as it seems to me, that a clear conception of the ultimate cause of all infection should be generally entertained. When all in-

fection is understood to be due to living micro organisms as its primary and essential element, all vague ideas of a relationship to poisonous chemical, physical, or atmospheric instrumentality will give place to more correct conceptions not only of what infection is, but also of what disinfection implies. The latter indeed is practically the most important of the two, for it is a familiar fact that people never do things so well as when they know why they should do them. The more thoroughly an enemy is known the more intelligently he is opposed, and when that enemy is known to be a living, though invisible, thing, what will destroy its life is seen to be more useful than to endeavor to counteract its doings. Another reason for defining infectious diseases as always due in the first instance to micro organisms, is that then it will be readily appreciated how their modes of propagation may vary widely according to the life-history of each species, rather than by only the one mode of contagion. Thus miasmatic diseases will easily be seen to be totally non-communicable as well as non-contagious, because yellow fever, for example, is not derived from an animal source, and only diseases from an animal source can be communicable to other animals. Again, with this conception of the nature of infection, it will not be difficult to demonstrate that some communicable diseases may be able to pass directly from one animal body to another, while others only indirectly, for so do seeds in all nature, even in the highest vegetable forms, present us with precisely analogous contrasts in the modes of their propagation. It has been asserted, for example, that but for the humble ground squirrel, hickory, oak, and chestnut trees would not be able to hold their own in our forests against the trees whose seeds can be carried by the wind.

The term communicable, seems to me particularly advisable to designate every disease whose origin as a disease is from some animal body previously infected with it, because this term will then fasten in the mind the fact that no case of such disease has any other cause than by such communication. This conviction of course does go with the word contagious, but it at once becomes very indefinite in all infectious affections where the term contagious is inapplicable. Hence some designation is particularly needful which will always mean danger to others, even if there be no evidence of contagion, and the word communicable, as we have defined it, does just that. Let a disease be known as communicable, whether contagious or not, and attention is at once awakened to the need of preventing such communication. Nothing, indeed, would so powerfully enlist general co-operation with us toward abating tuberculosis, for example, as to have every consumptive patient and his friends become assured that this distressing malady came to him, not *from* earth, air, or water (though perhaps by all three), but came instead to him originally from another consumptive. But I do not know of any other term than communicable which will serve this purpose, for all other terms which have been employed imply more or less the idea of contagion. Now we should not ignore the instinctive recoil of most persons against the word contagion. In an acute disease like scarlet fever, its dread presence is borne as well as may be on account of the hope that erelong it will be past. But for a chronic affection like phthisis, acting like the slow blight of a withering curse, to have it also thought of as contagious is so repellent to patients and to friends alike that every objection to the belief in such a doctrine will be sure to have its effect upon the mind. But with the designation communicable, but not contagious, the loving ministry of friends need in no way be checked by dread of touching the stricken one, while at the same time the name gives an effective note of warning against its further repetition in other persons.

It is with communicable but non contagious diseases, in fact, that a definite designating term is at present most needed to prevent ignorant fears on the one hand or ignorant carelessness on the other. It was a serious discredit to our profession, as well as to our civilization, that a passenger steamer was dealt with as the Normannia was in 1892, when, notwithstanding the great object-lesson which it gave that cholera is not a contagious disease, because not a single case of cholera occurred among its cabin passengers, though they were virtually nearer to it in an epidemic form among the steerage passengers than if they were all in a city tenement, yet no ship-load of small-pox patients could have been more summarily dealt with than they were. Meantime the absurdity of the usual methods of quarantine service in such a case was perfectly well known by us physicians. A single individual from that steerage crowd, with a slight choleraic diarrhœa, might have passed up to the Harlem Railroad as a laborer, and there infected the water supply of this city beyond the power of all the quarantine officials in the country to have remedied the mischief. But when confronting the New York State Senate Committee on Cities as a delegate from this Academy to lay these facts before that remarkable body of legislators, I found a state of mind and of intelligence in them on all questions about infectious diseases which one might expect from an equal number of Mohammedan muftis, and no more. In fact the chairman of the committee in reply, enunciated the old orthodox Moslem doctrine that God was himself responsible for whatever should happen on the Croton water shed, as he sent the rain which washed things into the river!

Again, what a commentary upon our contemporary medical knowledge is the following instance related to me only last week: A widely known and highly esteemed lady, resident in Princeton, N. J., died this past summer in Chicago, from typhoid fever. Arrangements for the funeral had all been made at her home, and prominent persons were chosen as pall-bearers, when the undertaker showed the husband a certificate that according to the laws of New Jersey public funerals were prohibited in the case of persons who had died of typhoid fever! In the case of tuberculosis the need of such a designating term as communicable is still more urgent as a warning against its most insiduous ways of gaining entrance. Thus a consumptive might not communicate the disease to anyone in his home, and yet so thoroughly infect his down town office by constantly expectorating on its floor, that he would communicate the disease to anyone who swept that floor, or even to another person who hired the same office after him.

Meantime I would restrict the appellation "contagious" to those diseases which are so directly communicable from body to body that mere proximity to the infected is ordinarily sufficient to occasion the disease in others. That these diseases should have a term which would adequately suggest this element in them is very desirable, because there should be no doubt in their case of the immediate necessity for isolation. This question of isolation indeed, overrides all others when it is raised, for it always means inconvenience and hardship at least, if not cause for widespread alarm. I can see no objection to the old term contagious, if we use it in the sense ordinarily understood by the public, namely, a disease which may be contracted by going near one sick with it, without implying anything else about its mode of communication. In this sense the term has become as settled in our language as any other English word, and on that account never can be displaced. It will always be used whether we medical men wish to retain it or not, while new words, however good, have to wait a long time ere it be known whether they will be allowed to become naturalized in a language or not. Moreover, the precise mode of communication has nothing to do with this term, or, for that matter, with any other designation of infectious diseases, for with the majority of these affections we are still ignorant of the precise mode of their infection, and hence we would have to wait indefinitely if we would postpone classifying them until we could define them according to their specific ways of entering the body. What we do know about those diseases which seem to pass directly from body to body is that whether

they pass in one way or another, they do so commonly only at short distances, and that fact is enough to justify the choice of a term like contagious, which sufficiently expresses the danger of approaching the infected, without necessarily implying anything else, while it also distinguishes them from the communicable but non-contagious diseases, in which the danger is as great, if not greater, at a distance than in the immediate neighborhood of the sick.

I have chosen the term septic to designate the third class of infectious diseases, mainly because of the familiarity of the public with the word as applied to what may be termed infections by inoculation. Antiseptic surgery has made the idea and the conditions of sepsis both widely and correctly known, and to my mind it is no objection to the term that its use in medicine is rather restricted to purulent infections, for tetanus and hydrophobia are as strictly inoculable diseases as pyæmia.

In this classification it is carefully stated that it is based upon the ordinary methods of propagation among the respective classes. That the active agents of some communicable contagious diseases may be carried to a distance by various media, as scarlet fever has been asserted to have been conveyed by letter, or in milk, does not militate against the statement that the usual mode of communication is by proximity to the sick. All infectious diseases probably can be communicated by inoculation into the blood, as it is claimed that ague has been so transmitted, but such wholly exceptional methods no more invalidate the designation of these diseases according to the normal modes of their increase than to object to certain plants being termed tropical because they are often found growing in green-houses.

Finally, it seems fitting to direct attention to the fact that all classes of infectious diseases are alike capable of being disinfected out of existence, because the public should be educated to the possibility of ridding the earth of the great cause of unhealthy places or climates, namely, miasmatic diseases. It is doubtful if an unhealthy climate as such exists on the globe, except in the Arctic regions from their extreme cold. Rather, it is not too much to hope that in the coming century the world will become so much wiser that a proper proportion of the enormous sums now wasted upon armies and navies will be transferred to sanitary bodies instead, with the result, already seen to be feasible, of disinfecting the soil by drainage and by other well known means until malarial fevers and affections will be matters only of history.

I have taken the liberty of bringing this subject before the Academy because it seems to me to be well within its province to take steps toward securing a uniformity in the nomenclature of the different classes of infectious diseases, such as would be justified by the present state of our knowledge on the subject, and which would greatly tend to the advantage both of the profession and of the public.

An Official Language.—According to one of the daily papers of Rome, a petition, signed by several hundred East Indian physicians, was presented to the officers of the Congress, praying that Latin be made the official tongue of all future Congresses. The signers also proposed the creation of a bureau in Rome for the publication in Latin of abstracts of all papers appearing in the leading medical journals of the world. Latin is not suitable for the purpose, it is too inflexible. Modern Greek is the language best adapted for an international medium of communication. We recommend a discussion of its advantages at the next Congress.

Syphilis in Tuberculosis.—The syphilitic infection prepares a soil well suited to the development of the tubercle bacillus, predisposing especially to pulmonary tuberculosis. It would appear that the syphilis, after the appearance of the tuberculosis for which it has prepared the way, decreases in virulence, or at least becomes latent.—Dr. P. Quidone, in *La Riforma Medica*.

INTESTINAL APPROXIMATION: ITS PATHOLOGICAL HISTOLOGY OF REUNION, AND STATISTICAL ANALYSIS.[1]

By J. B. MURPHY, M.D.,

PROFESSOR OF SURGERY AND CLINICAL SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO; PROFESSOR OF SURGERY, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO, AND PRESIDENT OF, THE MEDICAL STAFF OF COOK COUNTY HOSPITAL; ATTENDING SURGEON TO ALEXANDER BROTHERS' HOSPITAL; CONSULTING SURGEON TO HOSPITAL FOR CRIPPLED CHILDREN; FELLOW OF ACADEMY OF MEDICINE, CHICAGO, ETC.

(Continued from page 663.)

It is a fact that in certain forms of intestinal occlusion (strangulation ileus in contrast with obturation ileus) a definite portion of the intestine suffers from an abnormal fixation and distention, which on inspection can be recognized by the asymmetry of the abdomen, and determined and outlined by careful palpation.

The one pathological condition from which it is most difficult to differentiate ileus is perforative peritonitis, but there are two symptoms upon which great reliance may be placed.

1. *In the early stage of perforative peritonitis there is an elevation of temperature; in intestinal obstruction, no elevation of temperature.*

2. *In perforative peritonitis there is a paralysis of peristalsis over inflamed area; in intestinal obstruction there is a very great increase in the peristalsis,* which continues until necrosis of the bowel takes place or a peritonitis is developed. Frequent auscultation of the abdomen, as an aid to diagnosis of intestinal obstruction, is of as much value as auscultation of the chest in arriving at a diagnosis in pulmonary diseases. With the stethoscope, or ear, upon the abdomen, in the early stage of intestinal obstruction, there is a constant rumbling and rolling of the contents of the intestine, and manifestations of stormy peristaltic action. These manifestations are most marked at the seat of obstruction, and, indeed, the location of the obstruction can frequently be ascertained by these signs alone. If this peristalsis should momentarily subside, it can be brought on with increased violence by manipulation of the abdomen. A dose of opium will suppress the peristaltic action of the intestine for hours, while a chloroform narcosis does not interfere with it. It should therefore be impressed on every physician that no opiates should be given in acute lesions in the peritoneal cavity until the question of diagnosis is decided. In ileus, where active peristalsis has subsided and cannot be reproduced by pressure, it is an indication that peritonitis has ensued, and the prognosis of the operation is proportionately grave. A symptom of importance is a very circumscribed dulness near or at the seat of obstruction, due to accumulation in the proximal portion of the bowel,[2] and a meteoric distention of the strangulated loop itself, due to obstructed circulation and decomposition of its contents, producing a rapid gaseous distention and complete paralysis of the wall.[3] Kadar's experiments show that the distention of the strangulated loop is not due to gas and intestinal contents forced into the loop from the proximal side, as was formerly supposed, but is principally due to disturbances of the circulation in the intestinal wall, and consists of a uniform expansion of the entire intestine which is produced by, (1) thickening of the wall; (2) accumulations of fluid; (3) development of gas from fermentation within the loop. This condition he produced experimentally by ligation of the mesenteric vessels after a ligature of the intestine on the proximal side of the portion in which the circulation was obstructed, the distal end being free, still the intestine was dilated. This has great bearing in all operations of intestinal approximation, as it accounts for the paralysis and distention occurring where a greater portion of the mesenteric side of the bowel is removed than on the convex side.

The outlines of dulness in various intestinal obstructions given by von Zoege-Manteuffel are interesting and instructive. An irregularity on the surface of the abdomen,

[1] Read by special invitation before the New York Academy of Medicine, December 7, 1893.

[2] Schede, Schlange. [3] Von Wahl.

supported by an increased circumscribed resistance and tension of the underlying coil of intestine, points definitely to an obstruction at the seat of that distended coil—a local meteorismus.[1]

It will be admitted that a definite diagnosis of the pathological condition producing the obstruction may not be possible. Does that prevent us from operating? No. Will waiting help the patient, or will it even assist in making the diagnosis? No. Every hour lessens the patient's resistance and increases local destruction or necrosis. Still every day we meet with cases in which this policy of procrastination is pursued until the patient is moribund; finally, and unfortunately too often, we are forced to operate under just these unfavorable circumstances.

When we operate under these conditions are we warranted in abandoning the search for the cause of obstruction and its removal, for the establishment of an artificial anus? I think not. Saltzman states that laparotomies for ileus, with removal of cause of obstruction, up to 1883 had a mortality of 71.3 per cent.: simple enterotomy, without removal of cause, 67.3 per cent. So hopeless were the results of laparotomies with the removal of cause that such surgeons as Madelung, Mikulicz, Schede, Shoenborn, who were formerly strong advocates of this operation, abandoned it for simple enterotomy to relieve the obstruction. The indications for the latter operation they attempted to extend even with a slight percentage in its favor, and the comparative certainty that a second operation would be necessary. The establishment of a fecal fistula in this class of cases should be permitted only as a last resort in a profoundly collapsed patient, as we have now means at hand for removing the necrotic intestine and re establishing its continuity in a much shorter time than a fecal fistula can be formed. The more acute the attack and persistent the pain, the more pronounced the collapse, the more probable the existence of complete strangulation and local necrosis. There is, however, no positive symptom of necrosis.

If the foregoing principles are adhered to, the intrinsic dangers of intestinal obstruction can be reduced to a minimum. As a matter of necessity the surgeon must see the case early, examine it carefully, and must be allowed to name the time of operation.

If we were asked what we considered the greatest danger in intestinal obstruction, would the answer not be, not the ileus, not the gangrene, not the peritonitis, but the lamentable failure to make an early and correct diagnosis; or still worse, the lack of courage, having made it, to act upon it. In other words, the fault is not in defects in nature, whereby these accidents are permitted to occur, but in the doctor for allowing the lesions to progress unrecognized or unrelieved beyond the possibility of rescue by surgical interference.

Leichtenstern, Peyrot, and Treves have endeavored, through careful analysis and classification of the history, symptoms, and physical signs, to make a definite diagnosis of the nature of the mechanical obstruction and of the portion of intestine obstructed. Leichtenstern expresses his views as follows: "The object of our diagnosis before the operation is performed is to designate the anatomical and pathological conditions by the history, symptoms, and physical signs, and thereby to ascertain not only that an obstruction exists, but also the position, cause, and nature of the obstruction." In a few cases this has been accomplished, but in the great majority it was impossible to arrive at such conclusions with any degree of certainty, and I feel that Schede has expressed the condition exactly as it exists, and includes all that is of vital importance to operators in the following words: "The greatest difficulty rests, and will for a long time rest, in the diagnosis. I will not even once mention, in considering the diagnosis, the nature of the obstruction, nor the portion of intestine obstructed. I will be satisfied if in a given case, at a given time, the presence of an obstruction to the passage of fæces can be determined, which obstruction it is impossible to relieve by any other means than the surgeon's knife."

Dr. P. Poppert, of Giesen, comments as follows on the cause of death after operation for ileus: "The majority of cases of ileus are already severely depressed—yes, collapsed, when they come for operation; for this kind of depressed patients every long operative procedure, which is accompanied by extensive opening of abdomen and exposure of its contents, will prove fatal; consequently a large percentage of laparotomies of this class die shortly after the operation, from heart failure."

LATERAL APPROXIMATION.

	Cases.	Recoveries.	Deaths.	Not Given.	Mortality Percentage.
Suture	33	20	12	1	36.4
Suture with mechanical aids	23	18	5	—	21.7
Of these, bone plates	14	11	3	—	21.4
Robson's bone bobbin	1	1	—		
Potato plates	1	—	1	—	100.0
Robinson's raw-hide segmented plates	1	—	1	—	100.0
Abbe rings	4	1	3	—	75.0
Davis mats	1	—	1		100.0
Mechanical means, Murphy button	10	10			
Total	66	43	21	1	31.8

The operation of lateral approximation (anastomosis proper) is distinctly a modern operation, as it was first successfully performed by von Hacker, of Vienna, 1886. It rapidly gained adherents on account of the great mortality following the operation of circular enterorrhaphy, and on account of the many mechanical devices that were brought forward about that time, which were intended to simplify the operation; such as the plates used so extensively by Dr. Senn (originally suggested by Connell), Abbe's rings, Robinson's raw hide and segmented rubber plates, Davis' catgut mats, etc.; and finally, on account of the larger aperture that could be secured, by the lateral suture.

The objections to this operation after resection are:

1. The amount of time and the labor required, as both ends have to be closed with two rows of sutures, each row at least an inch long, necessitating four inches of suturing for the end, no matter what method may subsequently be used for the lateral apposition. Then the approximation plates or button is inserted. If the suture be used, it is advised (Abbe) that an opening four inches long be made, and around this be placed one row of Czerny and two rows of Lembert sutures; these rows will average about ten inches each, which, with the four inches of suturing required to close the ends, make thirty-four inches of suturing. For each inch four to six stitches are required, making a total of 136–204 stitches. An expert operator is able to do this operation in a comparatively short time, as Abbe has done, but how long would it take the average operator?

2. The danger of necrosis of the inverted portion at some point over this long space; this I consider of small moment.

3. The danger that one of the many stitches might penetrate the thin mucosa, as they must all include the tunica propria upon which it rests, and be exposed in the calibre of the bowel, producing stitch abscess (as in W. Rindfleisch's cases). The silk remains for an indefinite time.

4. The broad cicatricial mass and the one-half inch of surface-approximation produced by these three rows of sutures, might be expected to contract, as there is no juxtaposition of the incised edges of the various coats of the intestine. This is shown in the case of Salzwedel, lateral approximation of intestine with suture, and still it is *the only case* we found of post-operative stenosis of the intestines, showing that it is of very rare occurrence.

End to Side Approximation.—There are two places in the intestinal tract where this operation should always be

[1] L. Rehm, Frankfort.

given the preference: 1. In resection for cicatricial occlusion of the pylorus, the end of the duodenum should be joined to the side of the stomach. 2. Resection of the cæcum in adults on account of the inequality of size of colon and ileum. In the first case the food is allowed to enter the intestine in about its normal position, and duodenal digestion progresses about the same as if no operation had been performed; of still greater importance is the fact that by this method the bile and pancreatic secretions are not permitted to enter the stomach and cause such grave disturbances as are reported to have occurred (Dr. Heinrich Braun). He considered the condition so grave that he suggested an operation involving a triple anastomosis to prevent the bile from entering the stomach. Lauenstein recommended this operation. End-to side approximation has no other legitimate place in surgery of the small intestine after resection.

End-to-End Approximation.—We note from the reports of cases in the last six years, 134 intestinal approximations by all methods, of which 49 were end-to-end, 61 side-to-side, and 24 in which the position of approximation was not stated. Of these, 44 cases were for intestinal approximation for acute obstruction, with 29 recoveries and 15 deaths; mortality, 34.1 per cent. For chronic obstruction 43 cases, with 31 recoveries and 12 deaths; mortality, 27.9 per cent.; making a total for obstruction of 87 cases, with 60 recoveries and 27 deaths; mortality, 31 per cent. The methods employed in acute obstruction were suture 28, recoveries 18, deaths 10, mortality, 35 6 per cent. Mechanical means 13, recoveries, 10; deaths, 3; mortality, 23 1 per cent. Suture with mechanical aid, 3 cases, with 1 recovery and 2 deaths; mortality, 66 7 per cent. Methods employed in chronic obstruction were, suture, 28 cases; 19 recoveries, 9 deaths; mortality, 32.1 per cent. Mechanical means, 13 cases; 11 recoveries, 2 deaths; mortality, 15.4 per cent. Murphy button, 20 cases, 19 recoveries.[1] Suture with mechanical aid, 2 cases; 1 recovery, 1 death; mortality, 50 per cent. Total number of intestinal approximations for closure of artificial anus, 35; 28 recoveries, 6 deaths; 1 unknown; mortality, 17.1 per cent. Of these 24 were suture, with 18 recoveries, 5 deaths, 1 unknown; mortality, 20.8 per cent.; 7 were by mechanical means, 7 recoveries; 4 were by suture with mechanical aid, 3 recoveries, 1 death; mortality, 25 per cent.

End to end approximation of the bowel is the most desirable position, as it most closely approaches the natural condition. Surgeons have always regarded the end-to-end as the ideal approximation. This was only deviated from with the hope of reducing the great mortality that resulted with the methods heretofore employed. Has this deviation accomplished the desired result? Our statistics answer, no. In forty-nine cases of end to end approximation by all methods, the above statistics show a mortality of 16 3 per cent.; while in 66 lateral approximations by all methods the mortality was 31.8 per cent. Results of the lateral approximation, therefore, show a mortality about one hundred per cent. higher than that of end-to-end approximation.

Paul remarks that; "end to-end is preferable to lateral union, if it can be obtained with equal safety." The objections raised to the circular suture are: first, the time consumed; second, the possibility of perforation in parts not covered with peritoneum (mesenteric attachment); third, the large number of sutures, and the liability that some of them would go through the entire thickness of the bowel and produce peritoneal infection; fourth, with the invagination method there is the additional danger of a post-operative progression of the invagination, finally producing obstruction; fifth, the danger of obstruction from contraction of the necessarily broad cicatrix.

While these objections have force against the end to-end approximation by suture, not one of them is valid against the use of the button.

Abbe favors the lateral approximation by suture in the following words: "Lateral anastomosis properly done, is eminently the safest and the best method of restoring the canal in most cases." The statistics of lateral anastomosis do not sustain this statement. Our statistics show a mortality in lateral approximation of 34.4 per cent.; end to end approximation, 16.3 per cent.; of this the mortality with suture was 20.6 per cent.; with mechanical means—the button—100 per cent.

The first objection to the button is that it is a foreign body in the intestinal tract and might cause obstruction. This accident has not occurred in one of the 32 cases operated upon, nor has it taken place in over three hundred experiments, nor will it occur except where there is a pathological contraction of bowel. The second objection that the necrosis of the tissue within the clasp of the button would be a source of danger, is purely mythical. There is no more danger from its infecting the peritoneum than from infection through the bowel by a piece of undigested meat; as the bowel is securely sealed *par excellence* by this method. Infection has not occurred in a single case. The third objection that the small surface of apposition would not prove adequate in the protection of the peritoneal cavity, has as little basis as there is for believing that the wall of the intestine itself is not strong enough to protect the peritoneum, as the pathologists show, in slides herewith submitted, that the intestine at the seat of approximation can scarcely be differentiated from the normal intestine. I have received no information, nor do I know of a case in which there was a failure of union by the button, nor do I believe that such failure will occur except where there is a septic peritonitis *due to infection from without.* The contraction of three-eighths of an inch in the opening, reported by Keen in his case, is in unison with the contraction of the bowel from its previously distended condition, and should be expected under these circumstances. But there is no proof that the contraction would have continued to complete closure, as occurred with the bone plates.

Two years have elapsed since the first operation with the button, in many others over a year, and in a still greater number a shorter period of time. I have received recent reports on many cases, and stenosis has not occurred in a single case.

I here append a synopsis of the cases of intestinal approximation as furnished me by the operators:

Case I.—From Dr. H. O. Walker, of Detroit, Mich. Diagnosis: Fecal fistula following laparotomy. Several unsuccessful attempts by other surgeons had been made to close fistula; laparotomy, December 8, 1892; excision of about four inches of portion of bowel involved in fistula; end-to-end approximation by Murphy button; time consumed in performing operation, seven minutes; patient made an uneventful convalescence, and in a letter received from Dr. Walker this month, he states that she has been in excellent health since operation, about one year ago. This was the first case of end-to end approximation performed on human subject by Murphy button.

Case II.—From Dr. Hoelscher. Mrs. L., aged thirty-two. Diagnosis: Annular stricture of rectum, situated three inches above the sphincter, which would scacerly admit the tip of finger.

Operation by Dr. Murphy, January 14, 1893.—The sphincter split down to the bone, half of the Murphy button passed up above the stricture. Incision united with sutures. Other half of button placed below the stricture and button pressed together. This produced a necrosis of the cicatricial tissue constituting the stricture, and an end-to end union of the rectum. The special button used was one and a half inch in diameter, and was voided on the twelfth day. Patient was seen three months after operation, and there was but very little contraction.

Case III.—From Dr. W. W. Keen, of Philadelphia. Mrs. P——. Diagnosis: Carcinoma hepatic flexure of colon.

Operation, January 30, 1893.—For repair of artificial anus and re establishment of continuity of bowel. Enterectomy of portion of bowel involved in fistula; suture

[1] Cases were added since table of percentages was made.

of distal end of ileum with Cushing's right angle suture; united proximal end of ileum to side of colon with Murphy button (middle size); closed abdomen; recovery. In writing of this method, Keen says: "The speed and certainty with which an anastomosis can be made, once that the bowel is prepared for it, are certainly advantages which the button possesses over every other means of anastomosis, whether by simple suturing or by bone plates, catgut or other rings. The question of speed in such abdominal operations is of the utmost importance, and this device is by far the quickest of all means of anastomosis." For an excellent review of the method and detailed report of this case, see *Annals of Surgery*, June, 1893. This was the first case of end-to-side approximation with Murphy button.

Case IV.—From Dr. G. D. Thomas, of Chicora, Pa. Mrs. H——, aged fifty. Diagnosis: Fecal fistula with stricture of bowel.

Operation, March 25, 1893, by Dr. R. S. Sutton, of Pittsburg.—Lateral approximation was make with Murphy button (largest size); bowels moved twenty-four hours after operation; on and after the sixth day bowels moved regularly, the constipation from which the patient had suffered having been overcome; fecal fistula closed in three weeks without operation.

August 11, 1893.—Patient continued in excellent health, being robust and going about her household duties. This was the first case of lateral approximation by Murphy button.

Case V.—From Dr. E. Wyllys Andrews, Chicago. Mrs. F. F——, aged thirty-eight. Diagnosis: Strangulated right femoral hernia.

April 3d.—Herniotomy; gangrene of eighteen inches of ileum; excision, end-to end approximation with Murphy button (middle size); mass dropped into the abdomen; procedure rapid and easy; no drainage; bowels moved fifth day; nineteenth day, button voided in normal stool; patient discharged April 23, 1893. November, 1893, patient in perfect health.

Case VI.—Dr. Murphy. Mrs. E. T. S——, aged fifty-three, in consultation with Dr. Fortier. Diagnosis: Dermoid cyst, intestinal obstruction. Patient removed to Post-Graduate Hospital; laparotomy by Dr. Murphy, June 2d, three days after onset of symptoms. Intestines found adherent in two places to dermoid; but this did not produce the obstruction; cyst removed; obstruction located, a circular band completely occluding small intestine; two inches of intestine excised; approximation made with Murphy button, mass dropped into abdomen. Time for making resection and approximation, five and a half minutes; time for whole operation, including complete closure of abdomen, nineteen minutes. Patient made uneventful recovery; temperature never reached 100° F.; bowels moved every day after operation; button voided on nineteenth day.

December 2, 1893, patient in excellent health.

Case VII.—Dr. Murphy. Mrs. K——, aged forty-eight, admitted to Post-Graduate Hospital July 10th. Diagnosis: Strangulated umbilical hernia, peritonitis; laparotomy same day; resection of four inches of gangrenous bowel which had perforated within the sac, and contents had escaped into peritoneum; approximation with Murphy button. Time for resection and approximation, seven minutes; extensive peritonitis; gauze drain; death thirty six hours after operation. Autopsy, one hour later, showed perfect agglutination of bowel, so that the exact line of union could not be defined; specimen exhibited to the post graduate class.

Case VIII.—From Dr. Hugh McCall, Lapeer, Mich. T. H. P——, aged fifty-five. Diagnosis: Fistula from gangrenous hernia.

Operation, July, 1893.—Lateral approximation with Murphy button (largest size). On seventh day patient had a copious natural bowel movement, the first in seven weeks; the button was perfectly satisfactory in establishing the anastomosis.

Case IX.—From Dr. Bacon. Mrs. L——, aged thirty-five. Diagnosis: Specific stricture of rectum, beginning two inches above sphincter and extending up two inches.

Operation, July, 1893: Modified Kraske, exposure of rectal wall, which was denuded, folded upon itself; button passed on sixteenth day. There was some hemorrhage a week or ten days after the button passed. The result is very gratifying; the patient was examined May 20, 1894; found rectum of ample calibre, and the wall, which was previously dense, is now soft and pliable.

Case X.—Dr. Murphy, on September 10, 1893, at the request of Dr. Joseph Price, of Philadelphia, in the latter's private hospital, performed a lateral approximation for fecal fistula on Mrs. K——, in the presence of the members of the Pan-American Medical Association. Cause of fistula, strangulated femoral hernia; Murphy button (largest size) used in making approximation. Time from beginning of operation until completion of anastomosis six minutes.

Under date of October 24th, Dr. Price writes: "Your patient made a beautiful recovery and has gone home healthy and happy; her bowels act kindly, and the fistula closed without operation; passed button on twelfth day.

Case XI.—Dr. Murphy. Mrs. B——, aged forty-five. Diagnosis: Fecal fistula following laparotomy for tumor. Present at operation, Drs. Mayo and McGahey and members of the Pan American Medical Association.

Operation, September 26th.—Lateral approximation. Time, seven minutes; recovery. Fistula not yet closed.

Case XII.—From Dr. W. B. Rogers, Memphis, Tenn. Male. Diagnosis: Strangulated inguinal hernia.

Operation, October 11, 1893.—Herniotomy, removal of ten inches of gangrenous intestine, end-to end union with Murphy button (largest size). Button voided on seventh day. Patient up and about in four weeks.

Case XIII.—From Dr. H. O. Marcy, Boston, Mass. Male. Diagnosis: Cancer of upper portion of rectum; profuse and dangerous hemorrhage. Case had had a previous left inguinal colostomy.

Operation, October 16, 1893.—Removal of coccyx and two-fifths of sacrum; opened the peritoneum; divided meso rectum, which permitted the bowel to come well down, resected four inches of rectum, and joined it end-to-end with Murphy button (largest size); button removed with slight traction on twelfth day. Patient made uneventful recovery. Dr. Maurice Richardson congratulated Dr. Marcy on the result obtained in this case, and in commenting on it, said: "It would seem to indicate that by this means cases were amenable to treatment that were heretofore inoperable."

Case XIV.—From Dr. C. E. Ruth, Keokuk, Ia. A. W., aged five and a half. Diagnosis: Tumor of cæcum, obstruction of three months' duration; patient very much emaciated.

Operation, October 18, 1893.—The entire cæcum, with two inches of colon and three-quarters of an inch of ileum excised, together with the enlarged glands in the neighborhood; approximation of end of ileum to end of colon with Murphy button (smallest size).

Dr. Ruth[1] remarks: "This is the first excision of the cæcum, to my knowledge, in one so young, for intestinal obstruction due to neoplasm, and the first in which the Murphy button has been used to make the end-to end junction of ileum to colon, in the human subject. Pulse at end of operation, which lasted but a few minutes, 160. Patient made an uneventful recovery, and on November 4th left for his home, apparently in the best of health. In spite of the objections made to the Murphy button, these stubborn facts remain: 1, It furnishes the strongest junction known; 2, we do not need to wait five days to get strong union, it is immediately obtained with proper approximation of the segments; 3, in urgent cases nourishment can be commenced at once, which would be scarcely thought of in connection with any suture or plate device; 4, no foreign body is left permanently in the walls of

[1] Tri-State Medical Journal, December, 1893.

the gut or in the peritoneal cavity to cause subsequent trouble; 5, in anastomosis between the gall-bladder and duodenum; in the formation of biliary, gastric, or fecal fistulæ externally, and by Bacon's method of treating non-malignant strictures of the rectum, it leaves nothing to be desired; 6, if 'circular enterorrhaphy,' undoubtedly the ideal approximation, is ever justifiable, it is by this means, as it minimizes the objections urged against the operation, viz, weakness at the mesenteric attachment and subsequent contraction; 7, the union can be made in less time than by any other means, thereby greatly lessening the primary mortality. The objection has been urged that the opening through the button is not sufficiently large. In my case the smallest-sized button was used, and the immediate symptoms of obstruction were decidedly less than at any time during the three months previous to the operation, and the pain was also less, showing that there is no need to fear on that score. In the small intestines the contents, being fluid, will pass, and of course there will be no difficulty with the gas as far as the button is concerned. Of course, in the management of these cases it is presupposed that the surgeon would use ordinary intelligence in feeding after a resection of the intestine, and not diet his patients on food that could not be rendered fluid, or nearly so, in the small intestines. All the alimentary functions seemed perfect after the eighth day. On the fifteenth day he is dressed and walking about, apparently perfectly well. He is rapidly gaining in flesh and strength. Microscopical examination showed the tumor to be a large round-celled sarcoma."

Dr. Ruth's conclusions are based upon very extensive experimental research.

Case XV.—From Dr. A. I. Bouffleur, Chicago. Female. Diagnosis: Intestinal obstruction from strangulated femoral hernia, in which a herniotomy with enterotomy in gangrenous portion had been made two days previous without relieving the obstruction, making six days in all from beginning of strangulation.

Operation, November 11, 1893.—Laparotomy, excision of four inches of bowel at seat of gangrene and fistula, end-to end approximation with Murphy button (largest size). Time for resection and approximation, four and a half minutes, the quickest time in which this operation had been performed, notwithstanding the fact that the doctor had not used the button previously. Abdomen closed without drainage. Patient was very much collapsed at time of operation; however she gradually improved and made an uneventful recovery, having copious passages two days after operation.

Case XVI.—From Dr. A. H. Cordier, Kansas City, who writes as follows: "On November 16, 1893, I operated for intestinal strangulation (acute), due to a complete stricture of the ileum, from an old inflammatory band. The constriction had existed ten days previous to operation. I used the button, and am pleased to tell you that his recovery up to this date, November 27th, has been an ideal one. His bowels moved within three hours after the operation. This was my first experience with the button, but I have used rings, mats, decalcified bone plates, etc., and I must say that the button is the quickest, easiest, safest, and surest of anything I have so far tried."

Case XVII.—From Dr. Carl Beck, Chicago, September, 1893. Patient aged thirty five. Diagnosis: Cancer of pylorus, involving liver, pancreas, and mesentery. Maydl's operation, duodeno-jejunostomy, using Murphy button for anastomosis. Patient progressed nicely until the evening of the seventh day, when symptoms of peritonitis began and terminated in collapse the following day. Autopsy revealed a peritonitis; another cancer in the sigmoid flexure obstructing the same. The food that had been injected per rectum had ruptured the bowel at this point and caused the fatal peritonitis. The button, which was of excellent use in the operation, was found in place; perfect union over the entire circumference; no peritoneal adhesions around the point of union, nor in the neighborhood. I think if it were not for the complication of the second carcinoma, the case would have been a perfect success. As to the usefulness of the button, it has been a most beautiful illustration.

Case XVIII.—*Cæcectomy. End-to-end Approximation of Ileum to Colon, with Murphy Button.* (By Dr. Alexander Hugh Ferguson.)—"Mrs. X——, suffering with a cancer of the cæcum for many months, emaciated, cachectic, presented herself for relief of intestinal obstruction.

"Operation, December 11, 1893.—I decided upon the removal of the cæcum, lateral incision, adhesions severed, ligation of mesentery, excision of one inch of ileum, cæcum, and two inches of ascending colon, end-to-end approximation of ileum to colon with Murphy button. Button liberated on sixteenth day. Recovered."

Case XIX.—*Lateral Approximation of Small Intestine with Murphy Button.*—Mrs. McC——, aged fifty-seven. Several months previous suffered from strangulated umbilical hernia with necrosis of loop of intestine; enterostomy was performed, both ends of the bowel retained in the wound; since that time patient has had a continuous discharge of the entire contents of the small intestine on the surface of the abdomen.

Operation, December 12, 1893, by Drs. Charles McBurney and J. B. Murphy, in Sym's operating theatre. —Ends of intestine plugged with gauze as a guide to the loops to be approximated. Incision in median line below the openings; loops readily secured; largest button placed in position; time of operation, five and a half minutes. Button escaped nine days after operation, through fistula. Recovered, fistula still open.

Case XX.—*Fecal Fistula at Ileo-cæcal Region. Enterectomy. End of Ileum joined to Side of Colon with Murphy Button.*

Operation, January 15, 1894, by Dr. Alexander Hugh Ferguson, of Winnipeg, Manitoba.—Mrs. X—— suffered from a fecal fistula following an operation on the intestine. The ileum was severed from its attachment to the colon, a portion of the latter in which fistula was situated, was resected, end of colon sutured, end of small intestine joined with the button to the side of colon with Murphy button. The result was perfect and the button passed on the sixteenth day. Patient did not have an unpleasant symptom after the operation.

Case XXI.—*Resection of Six Inches of Sigmoid Flexure of Colon, with End-to-end Union with Murphy Button.* —Dr. Joseph Price, of Philadelphia, under date of February 13, 1894, writes as follows: "I did an unique piece of surgery on the 3d. I found an universally adherent cyst, malignant invasion of sigmoid—the bowel too strongly imbedded in cyst-wall for enucleation. I sev ered the bowel above and below the adhesions, leaving six inches of bowel on cyst-wall taking out a V-shaped piece of the mezzo-sigmoid. I placed in both extremities a puckering string, inserted a Murphy button, pressed it home; the work was quickly and beautifully done. By any other method it would have been a tedious piece of work. The result has been perfect. The button passed on the ninth day. Since July last I have had a run of over one hundred and forty sections without a death from any cause. The Murphy button saved one that would have been hopeless without it, so you see your button is helping to give me a nil mortality. Please order me a set and O.K. them, as my stock is exhausted."

Case XXII.—By Dr. Carl Beck, of Chicago. Diagnosis, fecal fistula. Operation, duodenojejunostomy. Fistula had existed for some time. The approximation was made two inches from the fistulous opening with Murphy button (small size); no inconvenience; convalescence uneventful; button discharged on twentieth day.

Case XXIII.—By Dr. Willy Meyer, New York. Mrs. L. P——, aged forty-three years. Diagnosis, carcinoma of pylorus. Operation February 24, 1894: resection of five inches of greater and three inches of lesser curvature of stomach; continuous Czerny-Lembert suture of end

of stomach; complete closure; resection of one inch of duodenum with pylorus; end approximation of duodenum to latero-posterior wall of stomach with Murphy button (largest size). Time for inserting button and making approximation less than eight minutes. Uninterrupted recovery. Button voided on twenty-first day.

CASE XXIV.—By Dr. Willy Meyer. Male, aged forty-six. Diagnosis, sarcoma of abdominal wall involving small intestine.

Operation, March 3, 1894: extirpation of a large fibro-sarcoma of abdominal wall with resection of fifteen inches of ileum which was infiltrated and twisted upon itself; end-to-end approximation by Murphy button; uneventful recovery.

CASE XXV.—By Dr. W. T. Dodge, Big Rapids, Mich. Boy. Diagnosis: fecal fistulæ, following gun-shot wound; two unsuccessful attempts to close the openings with suture had been made; the opening on the left side connected with the small intestine and the one on the right with the large intestine. The patient was rapidly emaciating on account of loss of nutriment.

Operation, January 2, 1894: incision on side of opening in small intestine; intestinal adhesions liberated and the intestines drawn out of the wound; resection of three inches at seat of fistula; end-to-end approximation with Murphy button; on eighth day the button escaped through the fistula in the large intestine. Recovery.

CASE XXVI.—By Dr. W. T. Dodge. Same patient as above. Operation, February 16, 1894: incision on side of fistula in large intestine; adhesions liberated; large intestine drawn out, resection of three inches; end-to-end approximation with special large-sized button. ("This button was ordered by Dr. Murphy for this case, its diameter of one and a half inch; diameter of central opening seven-eighths of an inch.) Having made the approximation I searched for the seat of the previous approximation. I found that it was not adherent to the abdominal wall and could only be recognized by the slight omental adhesions. It was of the same calibre as the rest of the bowel. The abdomen was completely closed. On the morning of the eighth day the button appeared at the sphincter and I assisted its escape. Perfect recovery."

CASE XXVII.—By Dr. W. T. Dodge. Female. Diagnosis, double ovarian cyst. "Operation, May 8, 1894. Cyst adherent throughout; it was found necessary to resect a portion of the small intestine. On end-to-end approximation was made with Murphy button; patient was very much shocked, but rallied from the operation; drainage-tube was kept in position; on the third day a fecal odor was noticed from the discharge; there was considerable nausea and vomiting; some fecal matter escaped through the wound on the fifth day; as the fæces were liquid I concluded the escape was from the small intestine. As the patient had considerable pain on the tenth day I opened the wound; soon found the small intestine at the seat of anastomosis, the union was perfect and the button gone; the opening from which the fæces escaped was found at the junction of the sigmoid and rectum. I made a colotomy. The patient died of shock the same night. While this case terminated unfavorably it has strengthened my faith in the Murphy button. The button was found in the rectum."

CASE XXVIII.—By Mr. A. Lane, Guy's Hospital, London. Diagnosis, sarcoma of mesentery of sigmoid. Operation, resection of tumor with twelve inches of large intestine; end-to-end approximation with Murphy button (largest size); gauze drain; button voided eighth day. Recovery. For details of this case see *Lancet*, April 21, 1894.

CASE XXIX.—By Dr. Joseph D. Bryant. Female. Diagnosis, fecal fistula of long standing. There had been several operations previous for its closure. The fistula was believed to connect with the transverse colon. Operation, May 9, 1894: lateral approximation of ileum to descending colon with oblong button (two and one-half inches in length); the button was easily inserted. Convalescence uneventful. Button passed on fifteenth day. Dr. Bryant was the first to use the oblong button on the human being, and I am much pleased to notice that it passed at such an early day, as the long button has a larger area of pressure atrophy than the circular one. Dr. Bryant will publish a detailed report of this case later.

CASE XXX.—By Dr. George Shrady. Female. Diagnosis, fecal fistula following gangrenous hernia. Operation, May 14, 1894: laparotomy in right inguinal region; lateral approximation with large-sized Murphy button; abdomen closed; perfect convalescence. May 26, 1894, operation for closure of fistula.

CASE XXXI.—By Charles McBurney. Diagnosis, tumor of cæcum. Operation, February 12, 1895, ileo-colostomy with Murphy button; infection occurred and a fecal fistula formed, on account of absence of adhesions; the button was removed through the fistula; a small fistula now remains. This report was furnished me by Dr. Gibney.

CASE XXXII.—By Dr. Robert Abbe, New York. Diagnosis, complete obstruction of colon by malignant growth. Operation, April 27, 1894, lateral approximation of ileum to colon with Murphy button, for relief of symptoms of obstruction, preparatory to extirpation of the growth. Convalescence was perfect.

Conclusions.—1. The more rapidly the operation is performed, the less the danger from shock.

2. The less the manipulation and exposure of the intestine, the less the danger of infection, post-operative paralysis, and adhesions.

3. The more uniform and continuous the pressure at approximation, the greater the assurance of adhesion and the less the liability of infiltration.

4. A line of approximation is as good as half an inch.

5. Mechanical means in the last five years have produced better results than the suture, in both lateral and end-to-end approximations.

6. The mortality in end-to-end approximations is much less than in lateral apposition, and should always be given the preference.

7. The more perfect the juxtaposition of the various layers, the less the interposition of fibrous tissue, and the more complete the regeneration across the line of union.

8. The juxtaposition of the similar histological layers of the wall of the intestine is an assurance against cicatricial contraction.

9. The more extensive the approximation surface, the larger the fibrous deposit, the greater the contraction.

10. The contraction with end-to-end is less than with lateral approximation.

(To be continued.)

The Lombroso Cure for Anarchism. The *Figaro* having asked Dr. Lombroso if he knows a remedy for Anarchism, the Italian *savant* immediately sent a reply, which the *Journal de Médecine* sums up in the following terms: "It must be treated by rendering it ridiculous." The same journal formulates prescriptions in accordance with the *savant's* dictum, with evidently more faith in their power of amusing their readers than in their medical efficacy.

THE EARLY TREATMENT OF SYPHILIS.

IN one form or another the question keeps continually coming up: How best to treat the early manifestations of syphilitic infection, and when to begin? More or less confusion has entered into the thought and discussion of the subject, from the conflicting observations of different syphilographers upon, first, the results of chancre excision, and secondly, the effects of very early mercurial treatment upon the subsequent course of the disease.

For one to arrive at a firm conviction by which he can be guided in his practice, it is important to have distinctly fixed in the mind just what the chancre signifies. He should also have a belief as to the nature of the virus, and a fairly clear idea of the relation which this virus bears to the subsequent manifestations, both early and late. Scientific research has resulted in so little positiveness upon anyone of these points that the individual is left to form his conclusions to a large extent from the accumulated clinical evidence, analogy, and deduction.

We know that after inoculation, within a period ranging in round numbers from ten to forty days, certain changes take place at the point of entrance of the virus, which are, in the great majority of instances, so characteristic as to be pathognomonic of systemic infection of a peculiar kind. It has been abundantly shown that at the time these local changes become manifest the system is no longer capable of a second inoculation. It is therefore evident that, while the elaboration is progressing which is to result in the local sign, there is also going forward some multiplication of the poisonous principle, which as such, or in some modified form, is to permeate the whole organism.

Excision of the inoculated point, to have any decided effect in checking this diffusion of the poison, must therefore be done at some very early period to offer any chances of success. Just when this period ends is naturally a matter of much uncertainty, for until the primary syphiloma appears there is no proof that the disease is present, and the preponderance of evidence goes to show that after the papule begins to form its excision does not prevent the usual eruptions and glandular involvement. Sufficient proof has, however, been adduced to encourage the early removal of the chancre, if it is so favorably situated that considerable surrounding tissue can be included in the cut—provided always that no neighboring glands show enlargement. It is highly probable that the general system becomes involved, not only through the lymphatics and blood-vessels, but also by contiguity of tissue.

If we presume the disease to be bacillary in origin, and that in some instances the bacilli wander into the neighboring tissues before they are carried to more remote ones, it follows that the only proper course to pursue in such a case is to remove the entire process with one stroke of the knife. Until it has been shown that such procedure never results in full prevention, or even marked attenuation, of after effects, the chances of benefit should be accepted for those initial lesions most favorably located.

Turning our attention to the medical side of the question, we find most authors and writers say, "Don't treat syphilis in the chancre stage;" and some even take no note of, and make no allowances for, those indurations, which may persist for months. Many say, "Postpone systemic medication until a secondary eruption appears," forgetting the many instances in which no early rash ever comes out, or is so slight that both physician and patient fail to note it. Others sound their warning to students, that mercury early employed causes grave lesions late in the course of the disease, and in the next breath advise local inunctions of mercurial ointment at and about the site of the primary induration. Little attention is often paid to the altered conditions when chancre and pregnancy coexist, and the imminent danger to the patient within the uterus, if treatment is put off too long.

Most certainly no one should treat syphilis any more than another disease before the diagnosis is made, but the common injunction, so often heard in the class-room, that one should wait for other manifestations, which, when they appear, are often as difficult of recognition as the primary, is too frequently an acknowledgment on the part of the professor that insufficient instruction in the diagnosis of chancre is provided by the college. That early treatment predisposes the patient to dangerous cerebral symptoms later on, is a question still to be settled, and until it is definitely disposed of it is safe practice to exercise common-sense.

COMMON FORMS OF DYSPEPSIA IN WOMEN.

THIS is the subject of the recent Ingleby Lectures, delivered by Dr. Robert Saundby, of which abstracts are given in *The Lancet*, March 17 and 24, 1894. These common forms of dyspepsia are well known, constituting the chief difficulty of nearly two-thirds of all the adult female patients who seek relief at hospital clinics. These particular conditions are not relieved by remedies set down in books, and originate chiefly in a neurosis dependent upon debility from anæmia or overwork. The nervous defect shows itself most commonly, or in its first and simplest form, by depression of the motor functions of the stomach and intestines; then by increased sensitiveness of the gastric mucous membrane; and, eventually, by diminution of the secretion from the membrane of the stomach. In the simplest form there is mere atony. Other forms present more serious features, of which vomiting is the most constant, due to gastritis or hyperæsthesia of the stomach. Hyperæsthesia of moderate degree may lead to serious impairment of health, and death may result from want of proper care.

Numerous experiments demonstrate that atony of the stomach, involving delay in the passage of ingesta into the intestine, is the most common, constant, earliest, and most important factor in the production of dyspepsia in

women. The defective movement of the muscular walls of the stomach results in the incomplete admixture of gastric juice with the food that it contains. The stomach becomes slightly dilated, and fermentative changes follow, together with attacks of subacute gastritis, known as bilious attacks. By degrees there is some atrophy of the gastric glands and consequent diminution of gastric-juice secretion. This initial evil, atony of the stomach, arises from many conditions: from anæmia, overwork, want of sleep, from anxiety, superlactation, absence of sufficient food, from irregular meals, too close confinement to the house, infectious diseases, and from want of fresh air, rest, and sufficient food during convalescence. The first indication in all these cases is to secure rest—rest in bed. Without it patients do not get well. Atony of the stomach is a condition due to exhaustion. Physical and mental power have been overstrained. The tax upon vitality must be reduced to the minimum. The period of necessary rest depends upon the intensity and duration of the symptoms. Sometimes thirty-six hours in bed will do wonders in the way of restoration, during the earlier stages; then, again, a week is required to bring about any real improvement; and it is often two or three weeks before the patient gains much, even when lying quietly in bed. Isolation from friends is not seldom imperative. Cases that are most obstinate and seem incurable will frequently yield to treatment when the unwise kindness of friends is made impossible. A change of scene and climate is of the highest value. Whatever exercise the patient takes should come in the early part of the day. Electricity, to stimulate the action of the muscular coat of the stomach and to restore its tone, is sometimes of great service. Either current may be used. Washing out the stomach, too frequently done in Germany and too seldom made use of in England, occasionally proves a valuable therapeutic measure. Emetics, however, according to Dr. Saundby, are to be preferred in most instances.

In regard to eating, the patient should be advised to eat everything she can without causing digestive disturbances. The regulation of diet depends upon definite special conditions. English and Irish women drink inordinately of tea, and the lecturer utters words of warning against this practice. Many American women, like the French, are inclined to the excessive use of coffee. The warning should include coffee in this country. But to forbid altogether the use of tea and coffee to women who never have enough to eat is both cruel and absurd. The order will certainly not be carried out, except under the restraints of hospital discipline.

The drugs that do the most good are strychnine, iron, bismuth, hydrochloric acid, and mercury. Abernethy defined biliousness as the condition that is curable by a blue pill. Whether it acts as an antiseptic or by unloading the vessels, or in both ways, is as yet unknown. Magnesium and sodium sulphate are the best aperients. Either may be given in the form of mineral water. Franz Joseph, Friedrichshall, and Hunyadi are the best-known magnesium waters; and Carlsbad, Kissingen, and Rubinat the most noted of the sodium waters. These sodium and magnesium salts or waters are to be taken in a pint of hot water on rising, if the patient is up and about, and in divided doses during the daytime if she is in bed. Rest, electricity, morning exercise, the regulation of diet—to be governed by the requirements of each case—the use of sodium and magnesium as aperients, and the judicious employment of one of five well-known drugs are the measures that this year's Ingleby lecturer advises, as the results of careful observation and a wide experience of the common forms of dyspepsia in women.

ANOTHER WORD ABOUT OUR ASYLUMS.

We are pleased to note that since our last issue the newspaper which recently attacked the New York City Asylum for the Insane has reached a clearer understanding as to the powers and responsibilities of the superintendents of that institution, and as to the handicap in the form of inadequate appropriations that is placed upon them; but we regret that it still seeks to hold the General Superintendent, Dr. A. E. Macdonald, responsible for some things over which he has, in point of fact, no control whatever. It ought to be generally known that Dr. Macdonald, during the entire twenty years he has served the Asylum in executive capacities, has persistently cried out against the restrictions placed upon his patients through illiberal appropriations of funds for their maintenance. His protests, his appeals, his arraignments of the Board of Apportionment, his attempts to reach the people in behalf of his patients, are matters of official record, as may be seen by anyone who will consult the printed annual reports of the Department of Charities and Correction. No one else has called attention as persistently as he to the fact that our insane dependents are inadequately provided for, and it is manifestly unjust to attempt to hold him responsible now for evils beyond his control, which he has so long and so loudly deplored. If we mistake not, he has more than once gone before the Board of Apportionment in person, to make his appeals for better shelter, clothing, food, and attendance for the insane. Is it his fault that the Board of Apportionment has chosen not to respond?

It should be known, too, that Dr. Macdonald has nothing whatever to do with the direct purchase of supplies, or with the placing of any contracts, either for supplies or for the construction or repair of buildings. He is therefore in no way implicated if it should be proven, as has been charged, that all asylum contracts are invariably placed with persons or firms of certain political affiliations. This very grave charge does, however, concern the Commissioners of Charities and Correction, and they should make haste to clear themselves, if possible, of an allegation so unpleasantly suggestive of malfeasance in the performance of their public duties. Our dependents and delinquents are charges of the entire city, not of any political party, and it is hard to believe that our Commissioners of Charities and Correction could be so lost to a sense of duty as to use the patronage of their department in the interests of a political machine. This certainly is one of the most serious of the charges brought against our asylum system, and the investigation now in progress should sift it to the very bottom. If it should appear that the patronage of our asylums is used, even indirectly, to bolster the dominant political party, that fact will be a strong additional reason for transferring the custody of these dependents from the city to the State. Independently of this matter, however, there are quite sufficient reasons for the transfer. The Commissioners

of Charities and Correction, even if proven altogether trustworthy, are utterly powerless before the Board of Apportionment, and that Board has repeatedly demonstrated its unfitness to act as custodian of the interests of the city's insane dependents. Whether the niggardliness of successive Boards of Apportionment has been due to indifference, to wilful ignorance, or to partisanship, does not greatly matter in the long run, for in any event their impositions upon this most pitiable class of unfortunates should no longer be tolerated by a humane people.

AN UNFORTUNATE VETO.

Governor Flower has vetoed the bill amending the public health law by adding to the civil penalties now imposed certain criminal penalties for practising medicine without legal authority. The governor says: "This bill is defective. To enact the bill in its present shape would be to destroy partially the wise principle upon which the public health law was framed and to establish a bad precedent for future legislation."

This bill was, we are informed, supported by the State Medical Society, and approved by the profession of the State. It simply provided penalties and rendered effective the present law regulating the practice of medicine. The veto of Governor Flower is a serious blow to the work of driving out quacks and ignorant practitioners from the State.

TO MAKE VACCINATION MORE EFFICIENT AND POPULAR.

Vaccination, as we are informed by a writer in *The Lancet*, is unpopular in the lower and middle classes (of London). It is, he adds, daily becoming more so, and then a suggestion is made for increasing the popularity and efficiency of the operation. A large proportion of vaccinations are inefficient and useless, owing to the antagonism of the patient and the carelessness of the doctor. Now Dr. Yarrow proposes to remedy this by having the government offer a fee of 2s. 6d., or about 62 cents, for each successful case. In this way vaccination will be more thorough, the results will be better, and the method will grow in favor. Dr. Yarrow and, we believe, English vaccinators are quite against the practice of vaccinating in only one place, and consider it an improper and inefficient method. Yet it is the one commonly pursued and approved in America.

We do not know that vaccination is getting unpopular in this country, but we are convinced that a great deal of it is imperfectly and carelessly done; and it is reported that the stock of virus used by health boards in some cities, including New York, is not very sure. Perhaps a prize for producing a good mark would be of use with us.

Bad Grammar and the County Medical.—The monthly notices of the New York County Medical Society read: "Members are respectfully reminded that in the discussion of papers each speaker is limited to five minutes, and will confer a favor by sending their names to the President." This is not very creditable to the literary attainments of a great and learned profession.

News of the Week.

The Death of Dr. Charles James, of Brooklyn, occurred, by a shocking misadventure, on Tuesday, the 22d inst. In the dark he seized a bottle containing tincture of aconite and swallowed a teaspoonful of the contents, instead of a medicine that had been prescribed for him by a colleague. The deceased was twenty-seven years of age and a graduate of the Long Island College Hospital Medical School.

Changes in Professorships Abroad.—M. Germain Sée, professor of clinical medicine, has been retired at his own request on account of the state of his health, and M. Chantemesse, *agrégé*, has been chosen to take his place until October 30th. Dr. Malassez has been nominated to succeed Professor Charcot in the chair of pathological anatomy. Dr. Joseph Gruber and Dr. Politzer, heretofore extraordinary professors of otology, at Vienna, and also Dr. Karl Stoerke, extraordinary professor of laryngology, have been made ordinary professors. Professor Czerny has been elected to succeed the late Professor Billroth.

Disease in Railroad Coaches.—In the laboratory of the Imperial Board of Health of Germany experiments were made, and the results which have been published show, says London *Science Siftings*, that the seeds of consumption were found in abundance in the dust collected, not only on the floors, but on the walls and seats of carriages. Samples of dust were taken from forty five compartments of twenty-one different passenger cars, and one hundred and seventeen animals were inoculated with them. Part of these died very soon thereafter of various contagious diseases, before they had time to develop consumption; of the rest, killed four to six weeks after inoculation, three had tubercles. These three, however, were inoculated with sleeping-carriage dust, taken, not from the floor, but from the walls, cushions, and ceilings. Bacteria at the rate of 78,800 per square inch were found on the floor of a fourth-class carriage, and 34,400, 27,000, and 16,500 per square inch on the floors of the third, second, and first-class carriages. Thus, even in the latter, the average passenger, who usually has at least half a compartment to himself, say 3,000 square inches of floor, has an army of 49,500,000 deadly enemies aiming at his vitals on the floor alone, to say nothing of other millions in front and rear, on both flanks, and overhead. It would seem impossible to escape; but a Board of Health is said to have reported measures for removing or reducing the danger, which the railroads are considering.

An Industrial Farm for Inebriate Women.—An English woman physician, Dr. Anderson Brown, has established an industrial farm for inebriate women, an experiment that will be watched with interest by all students of social economics, as well as the world of law and order. The test is to be made under the auspices of the Women's Temperance Association, and one of its chief features is to be the number of out-door occupations to be provided.

Surgical Instruments of Antiquity.—George Pernet, M.R.C.S., of London, England, writes: "With reference to the extract from my article 'The Armamentarium of a Gallo-Roman Surgeon of the Third Century,' *Medical*

Magazine, for April, which appeared in your issue of May 5th, under the heading, 'The Surgical Instruments of Antiquity,' will you allow me to point out that Dr. Deneffe is professor of operative surgery at the University of Ghent. He is not an Antwerp surgeon, as stated in your journal. As the information may prove useful to those of your readers who may visit Belgium at some future time, I trust you will be able to insert these few words in the columns of your esteemed and vigorous weekly."

The Treatment of Lead Poisoning with Monosulphite of Sodium.—M. Perou states that the administration of 40 centigrammes a day of monosulphite of sodium gives rapid relief in lead colic. He states that the elimination of the metal is much hastened by this treatment, and that the sulphite is an efficient prophylactic agent. The employment of the drug is, he says, devoid of danger.

Gold Cure Establishments Must be Under Medical Control.—An action has been taken by the College of Physicians and Surgeons, Quebec, against Father Murphy, he having opened and conducted "Father Murphy's Gold Cure Institute" for the treatment of inebriates from April, 1893, to September of the same year. The reverend priest claimed in defence that the institution was always under the control of a duly licensed physician. The court held that the proof went to show that the physician made only one visit and gave a single injection to the patients each day, the other injections being attended to by the defendant himself or his employees, notwithstanding the prohibition of the physician, and that the defendant practised medicine to the extent of giving them remedies and injections. For these reasons the defendant was held to have acted in violation of the law and was fined fifty dollars, and, in default of paying the same within thirty days, to be imprisoned for sixty days.

New Hospital Managers.—The Governor of New Jersey recently appointed the following gentlemen as members of the new Board of Managers of the State hospitals: Mr. George Richards, Dover; Dr. Romeo F. Chabert, Hoboken; Rev. Dr. J. M. Buckley, Morristown; Mr. George B. Jenkinson, Newark; Mr. Patrick Farrelly, Morristown; Mr. Lewis Parker, Trenton; Mr. Charles E. Green, Trenton; Mr. John Howe, Monmouth. The new Board appears to be made up of the right sort of material. The Rev. Dr. Buckley, editor of the *Christian Advocate*, of this city, is known to be a great friend of the insane, and for more than twenty-five years has manifested a warm interest in bettering their condition everywhere. With the advent of the new Board into power, partisan considerations will undoubtedly cease to pertain in the State hospitals of New Jersey. The present medical officers of these hospitals, who have so vigorously endeavored to keep the great charitable institutions under their charge beyond the grasp of political despoilers, ought to feel encouraged at seeing the dawn of what appears to be a new era.

Legal Requirements in Montana.—Dr. W. M. Bullard, secretary of Board of Medical Examiners, Montana, writes: "Dear Sir: I desire to correct the position given Montana in the article, 'Legal Requirements for Practitioners in Different States,' in the MEDICAL RECORD or March 24, 1894. We are proud to say that Montana belongs to the first class mentioned in said article; we require 'an extra and independent examination.' The applicant to practice in Montana must present a diploma from a recognized college, in order to be admitted to the examination, which is written and conducted by the whole board, so that with us a diploma of itself is no license to practise. Therefore please class us with the 'banner' States, making the list seventeen. I have not yet received the report of the Illinois board for 1894. The above facts were sent them, and I shall write the secretary at once. Our courts uphold us in the above rule, under which we have worked for over three years. Please give us notice of above."

Dr. John J. Gannon, one of the apothecaries of Bellevue Hospital, died in that institution, May 23d, aged forty-two. Dr. Gannon had been for seven years connected with the hospital, and had been in the employ of the Department of Charities and Correction a score of years. He was a graduate of the New York College of Pharmacy and also of the Bellevue Medical College.

Dr. George W. Brown, secretary of the New Jersey State Medical Board, whose home was at Long Branch, died on May 29th of consumption at the Trenton House, Trenton, N. J. He was a son of Ex-Mayor Brown, of Long Branch, and was thirty-six years of age. He was graduated at the College of Physicians and Surgeons. New York City, about fourteen years ago.

Medical Students in France.—Statistics prepared for the Budget Committee of 1894 show that the total number of students of medicine in France on January 1, 1893, was 6,470. Of these, 3,634 were registered in the Paris faculty and 2,836 in the various provincial faculties.

The New Mydriatic Scopolaminine.—Dr. Guttmann (*Therap. Monats.*) gives an account of numerous observations made by him with scopolaminum hydrochloricum in solutions of 1 in 1,000, 2 in 1,000, and 4 in 1,000. In the normal eye the second solution produced mydriasis maxima in ten to thirteen minutes, in the inflamed eye after ten to thirty-five minutes, four to seven days being required for the narrowing of the pupil, and three days for the return of pupillary reaction to light; fifteen to twenty minutes produced some anæsthesia of the cornea. The accommodation became paralyzed after three minutes, this condition reaching its height after forty minutes, when it was more intense than after a one per cent. atropine solution. In practice it was very valuable in keratitis, parenchymatosis, and iritis, but even the 2 in 1,000 solution was no more effective than a one per cent. atropine preparation. Scopolamine, being non poisonous, can be used every hour, and even under these conditions but rarely produced temporary dryness of the throat, which, however, required no treatment. It was thus most valuable in the case of children, in whom it can be used two or three times a day during long periods, and without unpleasant results.

A New Hospital in Iceland.—There appears to be a distinct want for a hospital at Isafjord, Iceland, and endeavors are now being made to meet it. A committee has been at work for some time in order to collect the necessary funds, and the plan is being warmly recommended by several Danish doctors who have visited the locality.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

EXTREME PROLAPSE OF FEMALE URETHRA IN A CHILD — URETERO LITHOTOMY—TUBERCULOUS DISEASE IN CHILDHOOD—ULCER OF DUODENUM—UTERINE CONTRACTIONS IN FIBROMATA, ETC —DIAGNOSTIC AIDS IN PREGNANCY —LAWSUITS—FOREST-GATE-SCHOOL SCANDAL.

London, May 12, 1894.

On Tuesday last Mr. Bryant brought before the Royal Medico-Chirurgical Society a case of extreme prolapse of the urethra in a girl aged six. The child had suffered at intervals of months from a discharge of blood stained mucus and irritation, but the attacks only lasted a few days and advice was not sought for them. When Mr. Bryant saw the case, on the fifth day of one of these attacks, there was a red protuberance which was determined to be an everted urethra. The next day, under chloroform, the urethra was dilated and the bladder explored with the finger with a negative result. The prolapse was reduced by this operation and the case did well. Some other cases, resembling this more or less, were related, one in which the surgeon, thinking he had a polyp to deal with, was about to ligature it, but happily before doing so passed his finger into the rectum, which reduced the prolapse. It is obvious that a protrusion of this kind may lead to error, and the possibility of such an occurrence must not be forgotten.

Two cases of uretero-lithotomy were then related by Mr. Cotterell, both in women, of the ages of forty-four and sixty-one respectively. The operative procedures were described, and some discussion took place in which Mr. Godlee, Mr. Reginald Harrison, and Mr. Henry Morris took part.

The last meeting of the Medical Society for this session was held on the 7th instant, when an interesting paper was read containing an account of some one hundred and twenty autopsies of tubercular disease in children. From this it appears that the disease usually commences in the glands in early infancy, the liability to it decreasing with advancing age. It was stated that it appeared to have commenced in the glands in no less than fifty-eight per cent. It was suggested that disease of the cervical glands might occur by infection through the blood, as in the case of joints, but that the bronchial and mesenteric glands might be affected by infection from the organ with which they are connected without a local lesion marking the entrance of the poison. The disease is more frequent in the thorax than in the abdomen in the proportion of 79 to 29. From the frequency with which caseation of internal glands is found after death this condition must often be unsuspected, and of course cannot be diagnosed. The chief point in management of those liable to the disease is to prevent its supervention. Some objection was taken to the proportion of cases of abdominal infection being considered settled It is often impossible to determine post mortem the point of entry of the poison, and we really do not know much, it was said, about the infectivity of food. Much must depend upon the dose of the poison, and when small there may be no local lesion. It was also remarked that the inflammation of the glands was only an effort to prevent general contamination.

After this discussion a case of perforation of the duodenum, due to a chronic ulcer and setting up acute peritonitis, was related. The ulcer was excised and the duodenum sutured with complete success, but when the patient was about to leave the hospital intestinal obstruction occurred. An operation was performed and the obstruction found to be due to a band of fibrous tissue. The patient sank, and after death other perforations and necrotic patches were found in the neighborhood of the fibrous band.

Are intermittent contractions of value in the diagnosis of pregnancy and uterine fibromata? Dr. B Hicks once again brought forward this subject at the last meeting of the Obstetrical Society. He attaches great importance to these contractions, and even holds that by their aid a diagnosis can be made between intra- and extra uterine fœtation. In the difficulty that sometimes presents itself when a single girl complains of stopping of the menses, he says the question of pregnancy can be decided without exciting suspicion by placing the hand on the abdomen and feeling a tumor with characteristic contraction and relaxation. So in a fibroid of the wall of a pregnant uterus, the organ will be found hard and firm on the one side and soft on the other during relaxation, but in contraction the whole becomes firm, proving the tumor to be uterine. So further, in twin pregnancy the uterus is of irregular form and like two tumors, but on contraction it becomes globular and is evidently one.

Some differences of opinion as to this sign were expressed and some scepticism displayed as to whether anything so precise and rhythmical as has been described could often be detected. Perhaps only those with large opportunities of practice can be expected to attain the required skill in manipulation, and I fancy few general practitioners would like to accuse a single girl of pregnancy after merely laying the hand on the abdomen in the manner mentioned. Even if he thought he detected the sign he would be doubtful whether his opportunities afforded him sufficient practice to be sure of his *tactus eruditus*. How few can form exact estimates of temperature or other sensations unless they are continually practising, and even then how often are they deceived.

Another case in the law courts illustrates the dangers of practice. A surgeon was sued for malpractice, and although his defence was triumphant the costs were heavy, and a subscription was raised to defray them. We are sadly at the mercy of dissatisfied and unscrupulous patients.

The scandal of the Forest-Gate school to which I have already alluded, has been the subject of a question in the House of Commons. The president of the Local Government Board replied that the irregularities, "though grave, were not fraudulent." Much dissatisfaction is felt at the answer, and the president is likely to hear more of the matter unless some decisive measures are adopted to protect the children from grave irregularities, though not fraudulent.

ON THE VALUE OF REST AND FASTING IN THE TREATMENT OF TYPHOID FEVER AND OTHER DISEASES.

To the Editor of the Medical Record.

Sir: In your columns of March 8, 1890, is an article from my pen under the head "On the Value of Absolute Rest and Starvation in the Early Stage of Typhoid Fever," in which I claimed that, by means of perfect rest and the withholding of all nourishment from the patient for a certain time, typhoid fever may be aborted in from eight to fourteen days; and that, thus treated, it becomes a comparatively mild disease, exhibiting none of the serious symptoms so prominent in that disease when it runs its usual course under the customary treatment.

As I therein claimed what no other physician had hitherto done, *i.e.*, a method of treatment by which, if seen early, any given case of typhoid fever may be aborted, I naturally became interested in everything said or written concerning that disease, with the object of learning whether the experience of any other physician or physicians tended to confirm my own.

Of course, I am acquainted with the fact that the ancients, both physicians and philosophers, distinctly taught that water was the only diet for fevers; and also, that previous to the teaching of Greaves, water-gruel only was prescribed under such conditions. I was the first, however, to point out that not only fasting or a water diet, but perfect rest also, are the most important factors in the treatment of typhoid fever and most acute diseases.

Since the writing of my article of March, 1890, from the medical journals at my command I have learned of the following confirmations of my own experience and observation.

In the London *Lancet* of September, 1890, is a very thoughtful and suggestive article from Dr. I. B. Nias, of London, on "The Value of Emaciation." In it, Dr. Nias, after demonstrating how, in many chronic diseases, emaciation is a conservative process, expresses himself thus on the treatment of fevers: "It would be well to consider the phenomena of waste in fever by the light of an assumption that they are salutary. The brute creation, when suffering from fever, eat nothing, yet they do not die, but recover. Great responsibility rests with those who supersede this instinct by an artificial method. Greaves, who fed fevers, at the same time bled his patients. The most evident of natural remedies for any kind of fever are starvation and emaciation. However indulgent appetite may be in health, it returns in disease to the strictest authority. Obedience to its dictates may shatter superstitions, but will not jeopardize the cure."

As bearing out the above remarks about animals abstaining from food when suffering from fever, I may state, that not long ago I had a marked proof of it in a little dog of mine, which absolutely starved itself for over five days, when suffering from an inflammation of one of its organs. Its treatment of itself—I interfered in no way—consisted of starvation for that number of days, a drink of water occasionally, and rest. This little incident, trivial perhaps to many, to me was very significant, as it served to prove that my line of treatment in such conditions is parallel with that manifested by instinct.

A second, or rather third, verification of my views I learned from reading a debate on typhoid fever at a society somewhere in a central State of America, I forget name and place. However, near the close of the discussion two aged physicians got up and calmly stated that they never found any difficulty in curing their typhoid cases, but that they never allowed any kind of nourishment to their patients until the appetite returned, a statement confirmed by one of them in a letter in answer to one I wrote him.

Again, about twelve or eighteen months ago I received a pamphlet from Dr. Laelbach, of Jersey City, a reprint of an article he had previously written in the *Medical News* on typhoid fever. The pamphlet being lost, I have to quote from memory. However, therein Dr. Laelbach plainly demonstrates that the amount of nourishment capable of being assimilated by the typhoid patient must be very small indeed, and remarks: "Actuated probably by that fact, Dr. Licorish, of Barbados, has urged in the New York MEDICAL RECORD the method of withholding from the patient all nourishment until the fever has subsided," and quotes several passages from my article bearing out his statement.

To come to later evidence. In your columns for November, 1893, Dr. G. Elliott, on an article in the treatment of typhoid fever, put in a very strong plea for the recognition of perfect rest in the treatment of that disease. As the doctor very pertinently remarks, physicians will say to themselves, "Everyone, unless he is a fool, knows that." But if they do know it, they do not put it into practice, for I maintain the rest contended for by Dr. Elliott and me is not that one sees in the ordinary treatment of typhoid fever by the vast majority of physicians, else they would value it and contend for it more than they do.

Again, in the last number of your journal received by me, that of February 24th, is an article by Dr. C. E. Page, of Boston, on fasting in typhoid fever and other diseases, which, except in the matter of the value of rest, bears out everything I urged four years ago; and certainly the doctor speaks in no uncertain tone.

Dr. Page, in his article, claims the experience of the forty-day fasters as bearing out his statements. In a paper of mine, published elsewhere, on the abortion of pneumonia by rest and starvation, I have this remark to the same purpose: "If the forty day fasters serve no other purpose than emphasizing the fact that starvation does not result in death within a little more than a week, as physiologists have hitherto taught, this must have a practical bearing on the treatment of disease, one which my treatment of acute diseases, especially typhoid fever, demonstrates."

It has certainly been a surprise to me that no practical lessons have hitherto been learned from the courage and fortitude first exhibited by an American physician.

As regards my method of treatment in other acute diseases, in none are its good results so manifest as in acute dysentery, the worst cases of which are brought under control within a week.

Analyzing, now, the evidence herein brought out in support of my views, it will be seen that it is chiefly on the side of starvation or fasting, as Dr. Page prefers to call it, and rightly so; I believe, though, for the other side, as to the value of rest, we have the experience of Dr. Elliott, an experience which must appeal to every thinking physician. Now, manifestly, the observations on either side are confined thereto, because the observers have only had their attention directed to one factor in the abortion treatment, whereas my observations, from the first, have been directed to both fasting and rest.

Since writing, four years ago, my further experience goes to confirm in every way what I then stated. I have, therefore, again to urge on physicians the practicability and benefits of my treatment, especially in the light of the experience herein mentioned in its support; for I am sanguine enough to believe that, when the value of rest and fasting in disease is recognized by the profession, it will constitute one of the greatest advances in treatment, and is destined to become of permanent value.

I may here state that two of my *confrères* in the island have tested the value of my treatment and proved its truth.

In justice to myself, however, I must draw the attention of Drs. Elliott and Page to my prior claim in enunciating the value of both rest and fasting in the treatment of disease, especially typhoid fever; a claim which, I have no doubt, they will hasten to recognize.

I am, sir,

Yours obediently,

R. F. LICORISH, M.D.

BARBADOS, W. I., March 20, 1894.

MEDICAL PRACTICE IN VAN, ASIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: After reading several articles on "The Taxation of the Incomes of Medical Men," "The Abuse of Medical Charity," etc., it occurred to me that a glimpse of practice in Turkey might, by comparison, lighten the dark places in American medical work.

As far as the written law, Turkey is perhaps the best governed land on earth; as far as the acting upon that law, she is certainly the worst. All doctors are supposed to be graduated or examined by the Imperial Medical College at Constantinople, whose officers are men of thorough training, and whose course is according to the German system, severe and searching. Once graduated, the young doctors are connected with some army corps, or made Belledier doctors, in charge of some city. Aside from these two classes Turkey has the benefit of certain quarantine doctors—German, French, Greek, Italian—as the case may be, who are sent out by the International Quarantine to protect Europe from cholera, etc. The men of these three classes are all educated, skilful physicians, and could the people enjoy their services there would be little need of medical missions or of foreign commiseration. But the doctors are few, their official duties are heavy, they are paid liberal salaries, and they do not care for work among the people. In this city of forty thousand inhabitants, with an immense outlying

district reaching to Persia, Russia, and Mesopotamia, there are four Turkish and one Italian quarantine doctors. The troops in Van alone number seven thousand, and after them and the small Turkish population comes the mass of the people, the wretchedly poor Armenians, who fall a natural prey to jugglers and old women.

For twenty years Dr. Raynolds, of the A. B. C. F. M., has done what he could for the people amid the pressure of his missionary work. In November, 1892, Dr. G. N. Kimball came to Van as a medical missionary, and I accompanied her as a free lance in search of experience. Every day since we reached Van, in the midst of a cholera epidemic, my opinion of the blessings attending practice in America has risen.

There is no dearth of material in Van. The records of 1893 run as follows: Individual cases of

Acromegaly	1	Otitis	20
Addison's disease	120	Respiratory tract disease	120
Bone disease	12	Rachitis	1
Disease of circulatory system	107	Rhinitis	3
Diabetes	2	Rheumatism	33
Dirt-eating	10	Skin disease	80
Eye disease	251	Surgical cases	14
Glandular disease	4	Syphilis	24
Graves's disease	1	Tuberculosis	23
Gynecological and puerperal	83	Tumors	22
Intestinal tract disease	254	Urinary tract disease	37
Liver disease	19	Zymotic disease	30
Nervous disease	50	Unknown	30
Total			1,419

Thus it appears that the line of cases is similar to that found in New York. Functional digestive derangements and malaria lead the list, with inflammatory diseases of the eye. The first is accounted for by the utterly irregular method of living, the fact that the main diet is "tonia" bread—thin, glutinous sheets—nutritious, but very trying when made the almost exclusive diet from one year to fifty, and finally, the half-starved condition of multitudes of the people.

Malaria would hardly be expected at home at an altitude of five thousand six hundred feet, but it revels in Van and in the mountain villages around. The pernicious type we have not seen, but we have had thirty cases of children under eight years whose abdomens were distended with a hard spleen that met the iliac crest and extended to or beyond the umbilicus. The tertian type of fever is most common. Our routine treatment is quinine sulphate, but in twenty cases we have used Warburg's pills, which have not failed thus far.

The prevalence of inflammatory diseases of the eye is explained by the intensity of the light on the wide plains and snowy mountains, the irritation of the smoke of the dung fuel that fills the houses each morning on lighting the tonia, and the universal and unthinkable filth of the people.

Of diseases not commonly met at home we have had a few cases of leprosy, occurring sporadically in distant villages, the disease being unknown to the people; and in two instances attacking young men who had never left their village homes.

Van contains one rare and perfect case of acromegaly, now fast succumbing to complicating diabetes. Hydatid cysts abound because of the dogs. Every native is the abode of lumbricoids that respond to calomel and santonine by the fifties and hundreds. By means of pumpkin seeds a tænia saginata over three yards long was removed from a boy of eighteen months, though the head was retained.

The frequency of dirt eating is hard to explain, unless it be due to the dirt that pervades all food here. Victims among the children may be told at a glance by the yellow, waxy skin, the anæmia being intense. Cases also occur of people who adopt the habit in middle life. Once acquired, dirt-eating has the tenacity of the opium curse.

Cholera raged in Van for six weeks at the close of 1892, being ended by severe cold weather. The infection was almost always to be traced to contaminated water; contagion was absent, and treatment by opium and stimulants was unsatisfactory. There may be more opportunity for treatment the coming summer.

A doctor sees few of the common zymotic diseases, the people thinking it foolish to call him for scarlet fever, etc. Small-pox rages unhindered, but as three thousand children died of it in 1892, there were few cases in 1893. The people expect an epidemic once in three years. The disease is almost unknown among adults, all having it in childhood. To it the city owes its many blind beggars.

For diagnosis Van compares favorably with New York as a field of practice. Beyond diagnosis all is vexation of spirit. It is almost impossible to follow a case. The people seldom call a doctor until they feel that the patient is dying. In five cases of prolonged disease we have been called just in time to see the patient die. If called earlier, and health does not return the day after medicine is begun, not one house in ten will summon the doctor the second time; and it is contrary to custom and etiquette and possibility to visit a patient without definite summons. Many patients are brought in from villages one to six days' journey away, and once seen, they return home. Chronic cases of office practice are somewhat more satisfactory, eye patients being especially willing to continue treatment. Even when fortunate enough to follow a case for some time, treatment is a hard matter.

Intelligence to act on instructions is found neither among Armenians, Turks, Syrians, nor Kurds. Bekir Effendi, one of the Turkish doctors, tells of giving a man a prescription for twelve powders of quinine. The man divided the paper into twelve parts, used some himself, gave others to his village friends, and finally returned for more paper, as that had worked so well. No surgical interference is possible, the people refusing even intubation for a child dying of diphtheria. On the other hand, accidental wounds, burns, frost-bites, etc., invariably heal with a rapidity almost miraculous.

The market-place tells one day of the doctors having taken out eyes, boiling them, and replacing them with vision restored; the next, how they gave a typhoid patient a powder that made him bleed to death before morning.

The question of diet they consider entirely outside the province of a doctor. If a typhoid convalescent craves "hartz-banir," the bread and cheese are given him. Babies revel in dried apples and nuts. A woman with phthisis refuses all animal food during the seven weeks' winter fast. A man with gastritis drinks arak before eating.

Finally, all you who sigh at the poor pay of American practitioners, read of medical fees in Turkey. An office call is 5 piastres, *i.e.*, 22 cents; a city call is 10 piastres; a village call—six to ten miles' horseback ride—is 20 piastres. At least half the work is charity, and even the half that pay the above rates pay only after long attempts to drive an Oriental bargain. All who pay do so in advance of any service rendered, for, once in receipt of the service, an Oriental laughs at an attempt to collect a fee.

But if picturesque and vividly colored thanks and blessings are desired, Turkey is the place in which to find them.

Louise Russell Smith, A.M., M.D.

Van, Turkey in Asia.

Clemen's Solution.—The following is the mode of preparation of the liquor arsenici bromatus used in the treatment of diabetes mellitus: Carbomate of potassium and arsenious acid, each one drachm; distilled water, ten ounces: boil until a clear solution is formed, and when cold add bromine, two drachms, and water, twelve ounces. This is allowed to stand until the color disappears, when it is ready for use. The dose is one to five drops once or twice a day.

PRESERVATION OF THE TEETH OF THE NEGRO.

To the Editor of the Medical Record.

Sir: After several years' residence in Central Africa I am of the opinion that the well-known excellent condition of the negro's teeth is not so much due to any peculiar physiological characteristic he may possess, or to his diet, as to the care which he bestows on them. That this condition of the teeth is not accounted for by the partial or total absence of meat from the diet of some is proven by the fact that others live almost entirely on meats. However dirty a native may be in other respects he always keeps his teeth scrupulously clean. It is well within bounds to say that a man will average forty-five minutes a day in doing this. On arising in the morning and after each meal he gives them a thorough washing, and at frequent intervals through the day they will be washed or scrubbed with dry sand or the "tooth-stick." This tooth-stick is a piece of root about six inches long, pared down to the desired thickness and one end chewed until well frayed out. They use it by rubbing it up and down the teeth, taking special pains to clean the interdental spaces. The native generally has one of these within easy reach. If he is travelling he usually has one stuck behind his ear; if not, he can borrow one from his companion. If he is at home, there are several sticking in the thatch of his low roof; while the stranger will find plenty in the village caravansary, ready for public use: after using, it is returned to its place without washing. I have frequently used the tooth-stick (not a public one) with complete satisfaction; the natives assure me that they improve with use. I am compelled to take their word for it, as I am not sufficiently communistic to borrow one from my neighbor or to use a public one. As the rural New Englander aids his imagination by whittling a stick, so the Central African will sit meditating (or vegetating) for hours at a time, all the while rubbing his teeth with a tooth-stick.

DR. SCHUMPERT'S CASE OF LOCOMOTOR ATAXIA

To the Editor of the Medical Record.

Sir: I noticed in your last issue an article by Dr. Schumpert, of Louisiana, upon locomotor ataxia, with report of a case which recovered from the disease. While I am pleased to see that he has endeavored to find a cure for the disease, yet I think he would not be justified in calling his case one of tabes from the symptoms presented in the article; which are "anæmia, heart disease, dimness of vision, and vertigo; for last two years tingling sensations and numbness in arms and legs, muscular weakness and girdle sensation. Still later he had paræsthesia of the four extremities and the gait was slow, faltering, and ataxic; pupils were dilated and knee jerk obtuse."

It seems to me that the only symptoms that can have any diagnostic value of tabes are, first, numbness and tingling sensations in arms and legs, which are also found frequently in other spinal diseases with cutaneous sensory disturbance. The girdle symptom is found in different forms of acute and chronic myelitis, especially when the cord, its membranes, or spinal root nerves in the dorsal segment are diseased, other than the posterior columns. Paræsthesia is a symptom common to other cord lesions as well as tabes.

I am unable to understand how the gait may be slow, faltering, and at the same time ataxic. The sharp, darting pains are not localized and therefore lose to a certain extent their diagnostic value. There is but a single mention of the so called patellar reflex, which was that the "knee-jerk was obtuse." I apply the meaning of obtuse as "not acute," that is, the foot subtended less than the normal arc, which would imply, at least, the presence of myotatic irritability in some degree. Most all authorities have agreed that the knee jerk phenomenon must be abolished in order to make a diagnosis of locomotor ataxia. I think, even when all the symptoms are grouped, the diagnosis of tabes extremely uncertain.

To summarize, the points of doubt of the diagnosis in this case are as follows:

1. The absence of syphilis as an etiological factor. 2. The few and uncertain tabetic symptoms. 3. The fact that the case recovered from the disease.

Sincerely yours,

L. Pierce Clark, M.D.

Connecticut Hospital for Insane, Middletown, Conn., May 22, 1894

ANSWER TO FAIR PLAY.

To the Editor of the Medical Record.

Sir: Anonymous letters should, I suppose, be always ignored, but as a matter of interest to those who may have read in the Medical Record of May 19, 1894, Fair Play's letter, I decided to relate Dr. C——'s side of the case.

Two weeks ago, on Sunday, about 2 P.M., I was at dinner with my family and one or two friends, and was called downstairs to see a well-known gentleman, who said: "My aunt is very sick, and the doctors who have seen her have decided that an operation is necessary to save her life, and I want you to get your instruments and assistants and come down prepared to operate." I asked him the names of the doctors.

He mentioned two; one, Dr. B——, I had met once and had heard of him, but knew nothing of his ability. I also asked the gentleman if the family wanted me to operate. He said yes, and besides, as he was the nearest male blood relation, there could be no question. Without saying more on the subject, as I had friends dining with me, I asked him to come up and take something to eat, as I knew him very well. The subject was not mentioned again till after dinner, when he found it nearly three o'clock, and he said he must hurry off to meet the other doctors. I said: "I'll have my assistants get everything ready, and I'll then follow you, and if I think an operation is necessary, I can send for them."

Now, nothing was said about a consultation, and I took it for granted that the other doctors had been told not only that I was coming, but that the family had decided to have me operate. A few minutes later I started for the patient's home. When I reached there I was introduced to the son in-law and a daughter or niece, and without a word of explanation was shown into a room where, to my astonishment, sat Fair Play and the two homœopaths. After shaking hands I sat down and listened to the two homœopaths give an account of the case; then, with Fair Play, I went and examined the patient, and returned to the other doctors and gave my view of the case. Then, to my surprise, the homœopaths began to get ready their instruments.

I saw that there was a misunderstanding, so I went out to see some member of the family and found the nephew, son in-law, and someone else. Without hesitation they all insisted that I must take charge and operate. I said, "Then you must explain this to the doctors," and the only advice I gave was for them to speak to Dr. Fair Play, as she was a relation, and would know what would be best to do. The two gentlemen saw the doctors, and when they came out they walked up to me, and in a very formal way, and asked me to assume entire charge of the case. I went in and spoke to the doctors and invited them to remain and see the operation. Dr. B—— said he had lost much time and could not remain, but the other homœopath did return and see the operation. I certainly did not mould the family or do anything unfair, or at least intend to do anything of the kind. I heard no objection from anyone; even Dr. Fair Play seemed perfectly satisfied, and she volunteered to go to her office and get a stomach-pump, which I thought

might be needed, as there was fecal vomiting, and the patient was seventy-four years old.

In talking to Fair Play before she left the house I said I would not have assisted Dr. B——, for I did not believe in assisting any operator, except in case of dire necessity, for any man to-day who is an expert in abdominal surgery should have his own assistants or he is not prepared to operate and give the patient the best chance. Well, the outcome was, Fair Play returned with her stomach-pump. I did not ask her to assist me, and when the patient was under ether I discovered that Fair Play had gone out. I sent one of the nurses for her, but she had left the house or refused to come in. This was the first inti nation I had that she might be offended, and I did not even suspect that I had done anything out of the way toward the other doctors till a letter came to me from her saying she had stayed away from the operation as a protest against my treatment of the two homœopaths, etc. As to Fair Play's statement, that I am "famed for obliging readiness to meet homœopaths," with many others of the regular profession. I consider it very poor policy to refuse to meet any doctor legally practising medicine. But, as a matter of fact, excluding the homœopaths I have seen when they have brought their wives for treatment, I cannot count all met in consultation on the fingers of one hand.

Now, Mr. Editor, if I had been called in consultation by either of the homœopaths, and had I gone, I certainly would not have operated, nor taken charge of the case; but I was called by the family, and according to the old Code I had a right to take charge of the case. I do not believe in homœopathy, yet my conduct in this case was not influenced by that fact; had all three been regular physicians I would have done the same. If I was wrong I would like to know it According to Fair Play, I don't see just how a patient is ever to get rid of a doctor.

As to proving the above facts about the case, I will produce the witnesses and appear before any tribunal that Fair Play may name. In her letter to me she admits a bitter feeling toward me about the only other case I ever met her in, and this must have influenced her judgment in this case. Strange to relate, meeting her in this other case was also a great surprise to me, for I had been told that she had been dismissed by the patient. Fair Play herself informed me she came to meet me in spite of the letter from the patient, for she knew it was all due to a meddlesome friend of the patient. I honestly tried to turn the patient back to Fair Play in this first case after the operation and danger to life was past, but I failed.

I still have faith to believe that Fair Play was blinded by prejudice and did not mean to be unfair. "Dr. C."

EXSECTION OF THE RIB NOT NECESSARY IN PYO-THORAX.

To the Editor of the Medical Record.

Sir: In your issue of May 19, 1894, Dr. Carl Beck refers in his paper on "Pyo-thorax and Its Treatment," to an article written by me and published in the St. Louis *Clinique*, with the remark, "The St. Louis *Clinique* does not disdain to draw classical rules from the observation of even two cases." The article alluded to distinctly states, in its text as well as in its title, that these two cases were appended simply as illustrative ones, their histories being published in full. Dr. Beck evidently failed to understand this, if he did me the honor of reading the paper. Should we reason from the doctor's paper in his own way, we should have to say he has not disdained to proclaim resection of a rib as the only successful method of treating pyo-thorax, from an observation of fourteen cases.

From the figures Dr. Beck gives us, it must be admitted he has had an exceptional number of these cases during his eleven years of practice in this country. The number can be better appreciated when it is known that St. Francis Hospital during the last seven years can only record seventy-four cases of empyema.

The method of treating empyema by free incision described in the paper published in the St. Louis *Clinique*, is that practised and taught by Dr. J. H. Ripley, and is the result, I venture to say, of a more extensive experience than even that of Dr. Beck. In the discussion following the reading of Dr. Beck's paper, at the meeting of the County Medical Society, the general opinion was that free incision with good drainage was all that was necessary in the great majority of cases, and only when this failed should exsection of a rib be practised. Our experience on the service of Dr. Ripley, at St. Francis Hospital, has been so favorable with the free-incision method, that up to the present exsection of a rib or ribs has not been found necessary.

Arnot Spence, M.D.

70 West Seventy-first Street, May 21, 1894.

New Instruments.

TYSON'S TATTOOING NEEDLE.

By H. H. TYSON, M.D.,

New York.

This instrument is designed to prevent the needles entering the anterior chamber of the eye, from any sudden movement of the patient's head, or too great pressure

from the operator's hand. The needles are 0.5 mm. in length (a trifle less than one-half the average thickness of the cornea), and set with a curvature equal to a radius of 7.7 mm., about the average radius of the curvature of the cornea. The handle being made of aluminum, is light and durable and easily cleansed.

47 West Fifty-first Street.

A NEW PORTABLE AIR-COMPRESSOR.

By JOHN NORTH, A.M., M.D., Ph.C., F.S.Sc. Lond.,

Toledo, O.

Professor of Diseases of the Nose, Throat, and Lungs, and Clinical Rhino-Laryngology, Toledo Medical College; Surgeon in Charge of Nose and Throat Department of Toledo Hospital; Consultant to St. Vincent Hospital.

Having been at a great disadvantage in attempting to make satisfactory spray treatments outside of the office, with the hand bulb and other devices to be used at the bedside, I set to work to devise some form of a portable air-compressor. I had examined and used the various appliances put on the market for that purpose. They all proved cumbersome and unsatisfactory.

The idea presented itself that the foot of the operator might be made to compress two rubber bulbs alternately, and thus produce a steady and constant current of air. After several attempts I succeeded in having constructed the portable air-compressor shown in the following cut:

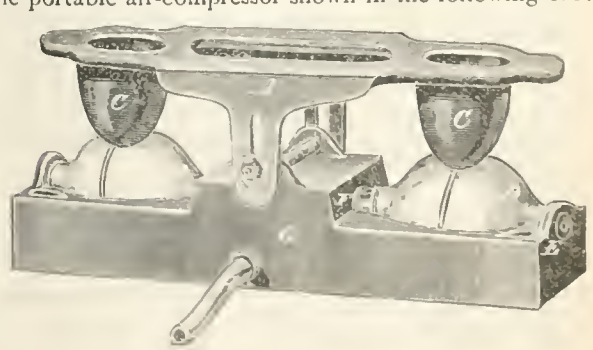

Fig. 1.

The machine is 10 inches long, 2½ inches wide, and 4 inches high. It is made of rubber and metal, and weighs five pounds. *A* is a pedal for the foot of the operator, with roughened top and heelplate (not shown

in cut), so that the foot will not slip. *B*, the arm of the pedal passing down on either side of the base of the machine. It has a long slot in it, so that the plungers will be raised off the rubber bulbs when the foot is removed from the pedal. The weight of the foot is sufficient to press the pedal down to the proper position. By alternating the pressure upon the pedal with the heel and toe, the bulbs are compressed and relaxed; while one bulb is being emptied, the other is being filled with air. *C*,

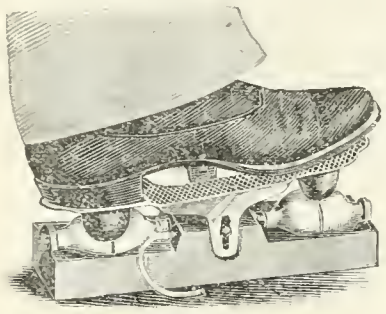

Fig. 2.

the plunger attached to the lower side of the pedal to compress the bulbs. *D*, represents two heavy double-necked atomizing rubber bulbs. *E*, a metal valve to allow the air to enter the bulb when the plunger is raised. *F*, a metal chamber valve which permits the air from the bulb to enter the air-chamber, and prevents the air from passing back into the bulb while it is being filled at *E*. *G* is an air-tight chamber to contain the compressed air, so that a steady and constant current can be produced. *H* is a rubber tube to conduct the compressed air to spray-producer, or for whatever purpose the machine may be used.

As the rubber bulbs and valves are strong, any desired pressure can be produced at the will of the operator. It is simple in its construction. It is always ready, and not liable to get out of order. It is convenient to use in the office, or can be carried to the bedside, being operated and controlled by the foot, which gives the use of both hands, an advantage that everyone will appreciate that has attempted to use a hand-bulb to produce a spray. It gives sufficient force to produce a constant and steady spray, with either oils or water solutions. Will operate any form of spray-producer. By means of it local anæsthesia is easily produced. Gives the operator the use of both hands in operating Paquelin's thermo-cautery, doing away with one assistant.

It is useful in operations when antiseptic sprays are desired. By attaching the rubber tube to a wash bottle sufficient force can be used to wash out the stomach, bladder, vagina, rectum, or any other cavity or portion of the body where a continuous stream of pure or medicated solution is required. By its use a steady blast of air can be produced to run a blow pipe. The ingenious physician or surgeon will find a great many other uses that it can be put to.

One great objection to air-pumps and air-receivers is the contaminated condition of the air produced by the rancid oils used in oiling the pump, and the decayed leather and rubber used in packing them; also the change and decomposition of the air that has been stored for a long time in the receiver.

This machine does away with all these objections, and a great many others that occur to those that have used the old methods. O. R. Bonnewitz & Co., of Toledo, have succeeded in constructing the machine for me.

I have had one in constant use for several months, and find it indispensable. I would be at a great loss without it.

HALE'S LIFTING COLUMN.

By C. A. PEABODY, M.D.,

SUPERINTENDENT OF CITY HOSPITAL, WORCESTER, MASS.

Among the many appliances and forms of apparatus that have been devised for changing the position of bed-ridden patients, and facilitating the application and renewal of dressings, etc., the one here illustrated answers the purpose better than any other with which I have had experience, and has points of excellence which merit the attention of the physician and the surgeon. Some of its points of excellence are:

1. It can readily be set up and taken down in any ordinary room without leaving a scratch or mark behind on floor, wall, ceiling, or furniture.

2. Its operation is very easy and safe. A young girl can handle a heavy man with it, changing his position or lifting him from one bed to another, which is all much easier and better than "calling in the neighbors to help."

3. The patient experiences no pain or discomfort in the movements made to change his position.

4. When extension is in use it need not be disturbed in moving the patient or changing his position.

There are many minor features which cannot well be described without taking too much space, but the essential characteristic of this apparatus is that which has given it its name, *i.e.*, the column or standard which, as will

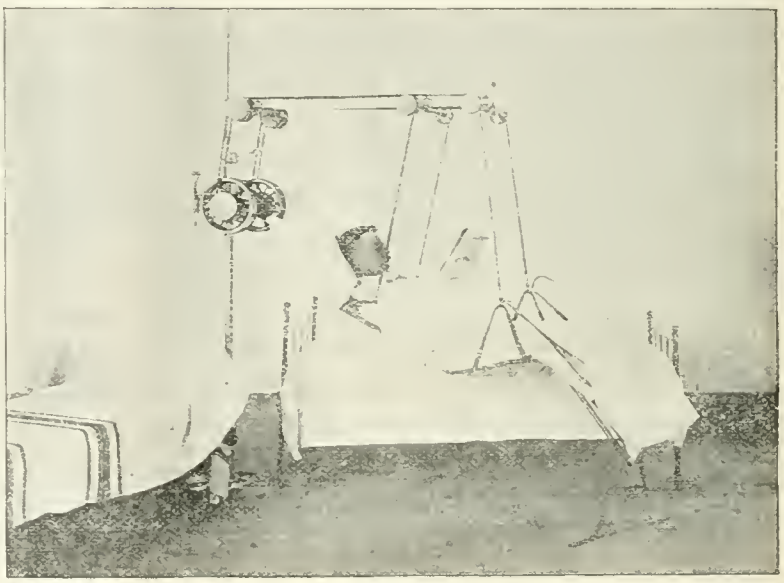

Fig. 1.

be seen in the cut, extends (on the principle of a jack-screw) from floor to ceiling, and supports a swinging crane by which the patient is lifted. The extremities of this standard are so broad that it is impossible to tip it over or displace it. The crane is secure against slipping or any accidental movement that would jar the patient, and it is sufficiently strong. It has been thoroughly tested in this regard by several men weighing from 225 to 260 pounds.

In use the patient lies upon a canvas-covered and jointed stretcher, which is placed upon any ordinary bed and covered with a sheet. The column stands behind the head-board (preferably), which should be low enough (say five feet from the floor) to allow the crane to swing over it; the whole apparatus then can be out of the patient's sight except when in actual use.

The straps which depend from the crane carry snap-hooks by which they may be quickly attached to the stretcher or detached from it. They are wound up on drums carried on the standard, by means of cranks and wheels, in such a manner that the stretcher (and patient) is entirely under the control of the operator, who can lift one side, one end, one corner, or the whole together, and put the patient into any position that may be de-

sired. The mechanism is very simple, and is not likely to get out of order or to need repair.

It was designed by the inventor for use in his own family, where it answered so good a purpose that it attracted the attention of several physicians and nurses,

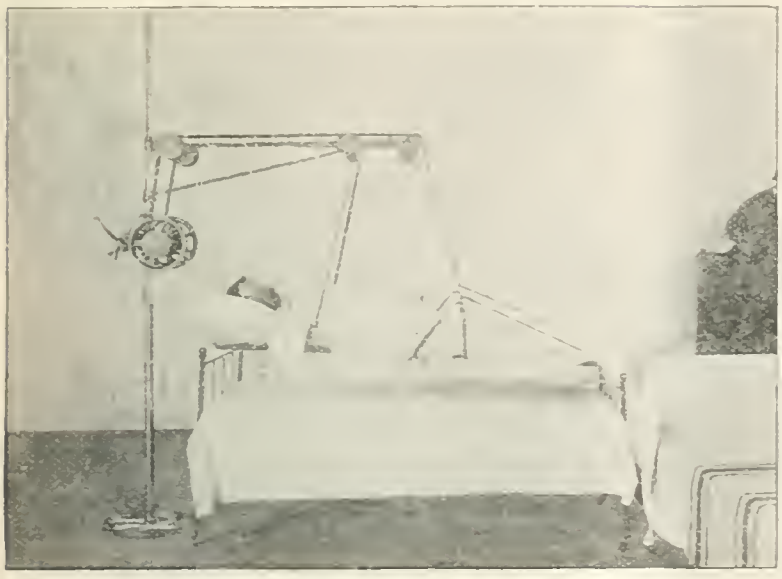

FIG. 2.

who urged him to arrange for putting it upon the market. He accordingly took measures to protect his invention, and has placed it in the hands of the Hartford Woven Wire Mattress Co., of Hartford, Conn., of whom the apparatus can be obtained.

Medical Items.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 26, 1894.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	5	3
Scarlet fever	151	15
Cerebro-spinal meningitis	5	5
Measles	133	8
Diphtheria	245	56
Small-pox	34	4
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

To Keep the Babies Quiet.—An English contemporary says that colliers' wives, in North Wales, gives morning doses of laudanum to their infants which suffice to keep the unfortunate little creatures unconscious until their own return from work in the evening.

Spanish Prizes.—The Spanish Royal Academy of Medicine offers its annual prize for the best essay on the following subject: "Clinical and Therapeutical Study of Chronic Affections of the Intestine." The A. E. G. Cano Prize will be awarded for the best essay on "Infectious Endocarditis." Essays may be written in Spanish, Portuguese, French, Italian, German, or English, and must be sent to the secretary of the Academy, 22 Montera, Madrid, before September 15, 1894.

Olive Oil is a popular domestic remedy in the south of France for nephritic colic. It is taken in tablespoonful doses every half-hour for six hours or until the pain is relieved.

The Necessity for a Well-paid Medical Profession.—In a recent address before the Southwest London Medical Society Mr. Thomas Bryant urged the importance of physicians being well paid for their services. He said (*The Lancet*): "Let us never forget that our patients' interests are those we should always primarily consider, and that in all our practical and scientific professional work the public good is its ultimate object; but at the same time let us bear in mind that in order to realize this leading purpose it is all-important for the interests of the public, as well as for the due exercise and dignity of our profession, that every practitioner of medicine should hold a perfectly independent but responsible position, and that in his professional work he should be left perfectly free from lay control, although amenable to lay censure. It is also equally necessary that he should be adequately paid for his professional services by all classes according to their means. Under these circumstances all measures, whether under the guise of charity or called 'provident,' and all hospitals, general, special, or private, which encourage the public to seek professional advice for little or nothing, are to be discouraged as helping to pauperize and degrade the public at large; and all members of our profession who induce or tempt the public so to do by means of private hospitals, competing private dispensaries, touting clubs, and associations, or who are ready to accept at a reduced figure, over the heads of their neighbors, appointments which have been put up by laymen, as it were, to auction or competition, adopt the surest means within their power to lower the position of their profession in the estimation of the public, and at the same time do injustice to the profession and public by not giving to the latter the best services the former can supply, while they must, in addition, lose their own self-respect, even if they happen to gain cash by their unworthy actions. For, let me ask, how is it possible for a man who is ill-paid or overworked, or both, either to give, in the interests of the public, the professional attention it is essential for him to bestow on every case he has undertaken to attend: or to maintain, in the interests of the profession, the position to which he is entitled and his own self-respect? We all know that any measure which encourages, either in a profession or trade, underpay and overwork, leads to bad work. In our profession such deficiencies are no less harmful—nay, they are more so, as its issues to the public are either life or death, health or ill-health, and to the profession either a position of pleasure, honor, and respect, or one of degradation and unrequited labor."

Leprosy in Germany.—According to the investigations of the Imperial Board of Health, whose attention was directed to the fact by a physician, there are at present ten lepers in the District of Mamel, Eastern Prussia. Eight other lepers died in 1877. Six of these eighteen cases were single persons; the other twelve extended over five families. Of those who died, two suffered from the disease eight years, others thirteen, ten, nine, seven, and one year. The first case occurred, as far as can be found out, twenty years ago. Only one of the eighteen had ever left home, so the origin of the disease cannot be found.

The Goddess of Small-pox.—A striking account of the difficulties attending on the attempt to extend the practice of vaccination in India is given by Surgeon-General Sir William Moore. The chief obstacle is superstitious prejudice. The population firmly believe variola to be matter under the control of the goddess Mata, in whose honor temples abound and fairs are held, where thousands of women and children attend with offerings. The

declivities of most of the numerous conical hills present either a reddened stone or temple devoted to Mata, with most probably an attendant Brahmin priest. Nearly every village has its goddess of small-pox in the immediate locality, and in many places a large piece of ground is esteemed holy and dedicated to Mata. The people do not pray to escape the affection, unless in seasons when it occurs with more than ordinary violence. They do, however, petition for a mild visitation. But even the loss of an eye does not appear to be viewed as a very serious calamity. "Is there not another eye sufficient for all purposes?" questioned one of these stoical philosophers. "If it were the leg or hand it would be different; but an eye is immaterial."

Postal Transmission of Small pox.—Dr. Karkeek, the health officer of Torquay, England, records in his report for last year the occurrence of two cases of small-pox in which the infection was conveyed by correspondence from a nurse in a small-pox hospital. One of the cases occurred ten years back, and the other last April, the patient falling ill two days after leaving Torquay. His friends had suggested risk from reception of letters written by a hospital nurse engaged in attending small pox cases, but he had pinned his faith on supposed disinfection of all letters. How far he was mistaken in his supposition was shown by the sequel.

The Medical Profession in the United States.—According to a recent report the total number of medical practitioners in the United States is 118,453. They are distributed among the several States as follows: New York, 11,171; Pennsylvania, 9,310; Ohio, 7,574; Illinois, 8,002; Missouri, 6,178; Texas, 5,288; Kentucky, 4,063; Tennessee, 4,379; Massachusetts, 4,457; Michigan, 4,057; Iowa, 4,434; Kansas, 3,089; Arkansas, 2,586; Maryland, 2,120; Virginia, 2,806; West Virginia, 1,061; Georgia, 2,725; Maine, 1,222; New Hampshire, 720; Vermont, 696; Rhode Island, 654; Connecticut, 1,267; New Jersey, 2,030; Delaware, 292; Indiana, 5,006; Wisconsin, 1,966; Minnesota, 1,584; Nebraska, 1,730; California, 3,300; Colorado, 1,165; Nevada, 66; Oregon, 909; District of Columbia, 831; North Carolina, 1,798; South Carolina, 1,422; Florida, 789; Alabama, 2,117; Mississippi, 1,782; Louisiana, 1,412; Arizona Territory, 108; Idaho, 176; Indian Territory, 416; Montana, 299; New Mexico Territory, 147; Utah Territory, 273; Washington, 910; Wyoming, 75; N. Dakota, 272; S. Dakota, 450; and Oklahoma, 267.

Removal of Bullet Imbedded for Thirty-two Years.—Dr. W. O. Roberts recently reported to the St. Louis Clinical Society the case of a man from whose thigh he removed a bullet which had been imbedded in the limb for thirty-two years. The man, whose age is fifty-five years, was struck by a shot just above the knee at the battle of Shiloh; the wound was probed soon after the battle to a depth of six or eight inches in an upward direction, but no bullet was found. He was in hospital for six months before the sinus closed. He then went back to duty, but becoming lame was again sent to hospital, where again free incision failed to discover the bullet. After this he had no further trouble till he came under the care of Dr. Roberts, who found a tumor about the size of a guinea-fowl's egg just at the outer side of the right inner hamstrings. This was cut down upon, and proved to enclose the bullet, which was covered on one side with a phosphatic deposit.

A Section of Medical Journalism.—The committee having in charge the creation of a Section of Medical Journalism at the next International Congress is chiefly Slavic in its composition. The president is Dr. Wicherkiewicz, of Posen, and the secretary, Dr. Mayzel, of Warsaw. The proposer of the resolution for the formation of the committee was Dr. Dobrzycky, of Warsaw. We decline all responsibility for the spelling of the names of these esteemed colleagues.

London has 5,590 regular physicians; Paris, 2,208; and Berlin, 1,799.

Primitive Comfort for Babies.—"The hygienic treatment to which Dorothy Drew, Mr. Gladstone's little granddaughter, is subjected," says a well-known writer, "extends so far that she always goes barefoot, indoors or out, except in very muddy or bitterly cold weather. Her dress and fare are of the simplest, and she is one of the healthiest, happiest, and most irrepressible of children."—Dr. C. E. Page, on "Summer Comfort for Babies."

Measles and Religion.—Dr. Gryglewicz reports an epidemic of measles occurring in the town of Jutrorchin. The inhabitants of the place are about equally divided between Catholicism and Protestantism, and the curious part of the epidemic was that only the Catholic children were attacked, every one of the Protestants, as far as could be learned, having escaped.

The Medical Women in Great Britain and Ireland number 186, of whom only 20 have thus far been admitted to membership in the British Medical Association.

Italian Cigars as Microbicides.—Dr. Tassinari says that the smoke of the "Virginia," the favorite cigar of the Italians, is inimical to bacteria. We should think it might be! It would kill an ordinary horse.

Insuring the Physicians' Lives.—The inhabitants of the province of Uriatka, in Russia, have recently inaugurated a system of insurance which we commend to the thoughtful consideration of all other communities throughout the civilized world. The locality being threatened with a recrudescence of the cholera epidemic, a resolution was taken by the influential men of the province to provide for the families of those medical men who might die from the disease. According to the terms of this proposition the family of any physician in active practice who may succumb to cholera will receive yearly the interest on 5,000 rubles, or on 8,000 rubles if the physician shall have been in practice in the province for a period of ten years prior to his death. This is an idea that is worth developing, and the insurance might be made to cover the death of a physician from any infectious disease.

The Gala Performance in Rome.—In the evening there was a gala representation at the Costanzi Theatre. The Italians have a novel conception of gala performances. They are a source of profit, being paid for by the members of the congress. The price of admission was doubled, and tripled, in honor of the guests. Even the daily journals were unable to conceal their amazement, and asked pertinently who it was that profited by this arrangement. What does M. Baccelli think of it?—*Concours Médical.*

A Hospital for Consumptives is to be erected in Philadelphia, to be under the care of the Bureau of Charities and Corrections.

Remedies that Cure is the title of a book recently published in Paris. An account of the remedies that do not cure would make a portly volume.

A French Hospital at Constantinople.—The cornerstone of a new French hospital was laid recently in Constantinople. It is to occupy the site of the old hospital on one of the finest squares in the suburb of Pera.

Music as a Healing Power.—The idea that music possesses an actual healing power is about to be tested in London. The Guild of St. Cecilia is about to build or hire a large hall, in which musicians, specially trained to sing and play the very soft music which alone should be administered to those whose nerves are weakened by illness, shall perform by day and night. Telephones will connect this composite and continuous music-room with certain wards of London hospitals. Records and data of conditions and effects are to be kept, and conclusions arrived at.

THE RECENT EPIDEMIC OF TYPHOID FEVER IN MONTCLAIR, N. J., AND VICINITY, DUE TO AN INFECTED MILK-SUPPLY.

By RICHARD C. NEWTON, M.D.,

MONTCLAIR, N. J.

WHILE epidemics of typhoid fever traceable to an infected milk supply are by no means unknown, the origin of few, if any of them, has been so easily and conclusively shown as that of the epidemic about to be described.

Nor in most cases has the epidemic ceased so quickly after the withdrawal of its cause.

Again, it must have been quite infrequent that cases of typhoid have been shown to have come from one exposure to the infecting principles, as happened in several of the cases in the Montclair epidemic. In what follows it is not intended to discuss in their various phases the questions of the etiology, diagnosis, and treatment of typhoid, but merely to give a summary of the cases, dwelling chiefly upon those aspects of the subject upon which the history of the epidemic seems to throw considerable light. Nor does it seem expedient at this time to load down this paper with a history of every case, nor even to print a tabulated statement of all the cases; although such a table could be furnished if necessary, and may be useful later on.

I will begin this paper with a short description of the dairy whose milk created so much havoc and distress in this quiet town, and furnished the daily press with much food for comment.

About a mile and a half from the centre of the town of Montclair is the dairy of G. W. G. It is situated in the town of Verona, upon the Pompton Turnpike. This dairy had a herd of sixteen or twenty graded cows, and supplied milk to about forty-four families in Montclair. The following description of the premises is given by an eye-witness:

"The entire place is in a disorderly and unkempt condition. The yard is filled with broken tools, odds and ends of wagons, sleds, and farming implements and litter of every description. The door-yard is ornamented by the droppings of fowls, and the same material embellishes the old wagons, harness, and tools, which are scattered about or gathered under two or three old sheds or outbuildings. As is the custom in so many country places, the privy is higher than the well. The lay of the land is especially adapted for the fouling of drinking-water, inasmuch as all the buildings are situated near the bottom of quite a smartly rising hill. The privy vault is filled with water to the level of the ground, and a little examination shows that the vault has been sunk in what appears to be a natural water course—namely, the sort of place that well-diggers would select to find water near the surface. About sixty feet below the privy is one of the wells of the establishment. It is not in a direct line below the privy, but is nearly enough so to be easily contaminated by the water, which is apparently nearly always flowing through the privy vault. This well, it is said, has not been cleaned for years, if ever. The water from it (it seemed to be about twenty feet deep) is drawn by a chain-pump, and was the water used in washing the milk utensils, bottles, etc. Another well is situated at the foot of the cow yard and at a lower level. A stream of urine from the cow stables, and excrement in suspension, seemed to be directed almost into this well, which it is alleged was used for watering the cows, when the third source of the water-supply was not so used. The third source is a cistern in the side of the hill, which contains alleged rain-water gathered from the roofs of the barns. This water runs into the cow stable through a faucet, and upon examination had proved to be badly contaminated with organic impurities. The cows were also said to drink from a filthy shallow pool in their pasture, in which they seemed to stand and lie, and which was fouled with their excrement and urine. The house-drain emptied into the surface of the ground near the street, and flowed along the side of the road."

On February 11, 1894, the seventeen-year old son of the proprietor fell sick. Dr. Love, of Montclair, saw this patient for the first time on the 18th. He had then been sick a week, and was not known to have seen a doctor before the 18th. The patient was dressed and lying on a lounge at the doctor's first visit. On the 20th the doctor saw him again and pronounced the disease typhoid. He gave the proper directions for the disinfection of the stools to the father, and also for their disposal—ordering them not to be thrown into the common privy, but to be buried, after disinfection, in shallow trenches.

The health authorities of Montclair were also notified of the occurrence of a case of typhoid fever at this dairy. They in turn notified the State authorities, who sent an agent to visit the dairy. It seems, however, that the sale of milk was not entirely stopped until March 29th. Why the State authorities did not act more promptly, or exactly what their power may have been in the premises, the writer does not know. At all events, an occasional case of typhoid on a farm in the environs of Montclair is no great rarity. And so far as the writer knows, no previous epidemic of any magnitude has ever been traced to milk anywhere in this immediate neighborhood.

So far as can be learned, Mr. G. carried out the instructions about disinfecting and burying the excreta from the sick boy. But his milk continued to be sold. A few days before this milk was entirely excluded from the market, another milkman, H. T., bought some of it and delivered it to his customers, most of whom lived in Bloomfield and Glenridge (communities immediately adjoining Montclair on the east). Inasmuch as G.'s milk was at that time under suspicion, H. T., to prove its innocuousness, drank somewhat freely of it. He subsequently took the fever and died. On March 29, 1894, as said above, the sale of milk from G.'s dairy was entirely prohibited, and so far as is now known, none of it has found its way into Montclair since.

This, however, was, to some extent at least, locking the stable-door after the horse had been stolen. Had the milk been promptly stopped on February 20th, it would have been very interesting to note the effect upon the spread of the fever. It seems probable that the milk was infected before the date mentioned, but in view of the fact that most of the cases of typhoid fever developed more than twenty eight days after February 20th (and twenty-eight days would seem to be the limit usually set to the period of incubation in typhoid), it seems fair to assume that most of those who had the disease would have escaped had the milk delivery ceased on February 20th.

The first case of typhoid in Montclair, and the second in the epidemic, occurred in the person of a little girl, three years old. She was first visited on March 12th, and had then been sick two or three days. So that there was an interval of twenty-seven or twenty-eight days from the beginning of the first case to the beginning of the second. This case ran an uneventful course for about two weeks, and terminated in recovery.

The third case in the epidemic was another son of Mr. G., aged about sixteen years. He was taken sick at the dairy on March 15th. It seems that all the family were actively engaged in the dairy work, and, it is presumed, drank the infected water and the milk also.

On March 16th two new cases appeared in Montclair (one of them, however, could not be traced to G.'s milk); on the 20th, four new cases, and so on until April 12th, two or more new cases appeared on every day, except April 10th, on which day none appeared. Between the dates given, March 12th and April 12th, one calendar month, one hundred and eleven cases of the fever appeared. Three have been reported since, which with the original case gives a total of one hundred and fifteen cases. These are all the cases that, after a careful and painstaking inquiry, are known to have occurred in Montclair, Bloomfield, Glenridge, and Verona during a period of about three and a half months, and all but eight of these were proved to have partaken of the milk from G.'s dairy. From a list of his customers, which Mr. G. kindly furnished, it appears that he regularly supplied forty-four families in Montclair with milk, besides leaving bottles of his milk at two or more grocery stores to be sold. Of these forty four families the fever appeared in twenty eight, or 63.6 per cent. In thirteen of these families there was one case of the fever apiece; in fifteen, more than one case. Of twenty cases reported from Bloomfield and Glenridge, eighteen were traced directly or indirectly to milk sold by H. T., and presumed to have been from the G. dairy. To my mind no series of figures could be more convincing. The epidemic came from just one source and from no other, and probably the first case at the G. dairy infected his own brother, and at least one hundred and seven other people. An analysis of the milk was made by Professor Leeds, of the Stevens Institute in Hoboken, and the following is a copy of his report:

"STEVENS INSTITUTE OF TECHNOLOGY,
HOBOKEN, N. J., April 11, 1894.

"GEORGE W. MCGUIRE, Esq.,
"*State Dairy Commissioner.*

"DEAR SIR: I transmit herewith report on sample marked 'N. J. Dairy Commission, No. 6851,' delivered March 31st by Inspector John C. Tracy.

"The sample was of whitish color and quite acid. Its specific gravity and total solids were quite low, the latter being 12.84 per cent. It contained:

Fat	3.87 per cent.
Lactose	4.95 per cent.
Albuminoids	3.30 per cent.
Ash	0.72 per cent.
Total solids	12.84 per cent.

"Besides the bacteria usually present in milk it had a number of those more especially found in water. The total number of colonies was enormous, being 2,187,000 per cubic centimetre. Though the specific bacilli of typhoid were not found in this particular sample, I regard the milk on the above showing as unsafe, and contaminated with impurities introduced subsequent to milking.

"Very respectfully,
[Signed] "ALBERT R. LEEDS."

Nor does the fact that no typhoid germs were found by Professor Leeds in G.'s milk have anything more than a negative significance. The difficulty of isolating and proving the presence of Eberth's bacillus in a suspected fluid being well known.

It seems that Professor Sedgwick did not find this bacillus in the water which contaminated the milk which was the cause of the Springfield epidemic of 1892, although he did find the bacillus coli communis in abundance. (See Twenty-fourth Annual Report Massachusetts State Board of Health.)[1]

Yet one can scarcely doubt that Professor Sedgwick located the cause of the Springfield epidemic in the well at the Feeding Hill Farm.

It is by no means necessary to prove that the milk is intentionally adulterated with infected water, and is thus contaminated with septic germs. The mere washing of the bottles or other containing vessels in polluted water at ordinary temperatures is quite sufficient. And the water in the cistern and both wells on G.'s dairy was proved to contain organic impurities and to be unfit for drinking. The analyses were made by Mr. D. H. Baldwin, chemist, Montclair, N. J. Mr. Baldwin also submitted samples of the water from these wells to the Health Board in New York City, and was told that under the circumstances the long and expensive process necessary to demonstrate certainly the presence of the typhoid bacillus in these waters was quite needless, inasmuch as there was no reasonable doubt that it was present in the water and had caused the sickness in Montclair. Mr. Baldwin was told the same thing at the Bacteriological Department of the College of Physicians and Surgeons in New York.

If any more proof were needed of the origin of the Montclair epidemic, the fact that but three cases of typhoid have appeared in the town since April 12th, and that this date was fourteen days after the total exclusion of the G. milk, would, I think, convince any fair minded man.

This paper has already transcended the limits to which it was intended to confine it. But the subject is so important that I trust I shall be pardoned for a few more remarks which seem, to me at least, of considerable interest.

Of the 107 cases 14, or thirteen per cent., have died. Upon one of these subjects an autopsy was secured, of which I will give the following brief account: The patient was a young lady, twenty-one years of age; she died after a relapse at the end of the sixth week from the beginning of the fever. An autopsy was made by Dr. R. P. Francis, of Montclair, assisted by the writer. The record is as follows:

May 17, 1894.—Autopsy sixteen hours after death. Body that of a well-developed young woman. Moderately emaciated. No external marks observed on body. Rigor mortis moderate. Some ulceration about shoulders and neck. Head not examined. On opening the body a moderate amount of subcutaneous fat was observed. Thorax: Diaphragm reached the fifth intercostal space on the left side and the fourth on the right. The muscular tissues were firm and free from fat. The sternum was short and the costal cartilages were long and their angles more than ordinarily acute. Pleuræ: No adhesions. Pericardium contains one-half ounce of reddish serum; normal to gross appearance. Heart: Muscles firm but pale. Right side contains some dark uncoagulated blood and had small chicken fat clots. Left heart empty; valves normal. Tracheal and bronchial glands not enlarged. Lungs normal except an infarct in left lower lobe as large as a black walnut. Abdomen: Omental fat present; some flatus in intestines. About four ounces of clear serum in pelvic cavity. There was no peritonitis. Spleen greatly enlarged; cuts like gritty material; "dregs-of-paint" appearance; weighs fifteen ounces. Intestines show spots of marked congestion. In the upper part of ileum a number of small superficial ulcerations, mostly of solitary glands. About one and a half dozen of Peyer's patches were ulcerated. The ulcers increase in area and depth as the cæcum is approached. One Peyer's patch near the ileo-cæcal valve is surrounded

[1] For the extreme difficulty encountered in demonstrating the presence of the Eberth bacillus, see paper on the "Differentiation of the Bacillus of Typhoid Fever," by George W. Fuller (Twenty-third Annual Report Massachusetts State Board of Health).

by a small gangrenous area. The gangrene may have been post mortem. The colon presents a great increase in the size of the solitary glands, so that its inner wall looked like a closely set cobble-stone pavement. Each follicle was about the size of a split pea. There was a considerable accumulation of fæces in the rectum. The appendix was normal. Liver about normal size, soft and pale, with the usual whitish areas observed in fever cases. Kidneys: Small capsules, non-adherent; on section, normal to gross appearance.

Cause of death, typhoid fever.

In conclusion, a few points of interest affecting nearly all of the cases should be mentioned. The oldest patient was seventy-two years of age, and the youngest eleven months.

An eruption was noticed in every case but two. One observer counted one hundred and fifty-seven petechial spots on a child of seven. This child and the young lady whose necropsy has just been related, had a very slight, extremely delicate desquamation over face and hands, which appeared as the fever was subsiding and remained two or three days. In another case the eruption was as profuse as in a moderately severe case of measles. (The petechiæ were innumerable.)

Diarrhœa was generally absent, all the observers agreeing that they had never met with so large a percentage of constipated cases.

Perforation: Only two of the fourteen fatal cases died from peritonitis, probably due to perforation, although autopsies were not held.

Relapses were quite common. Thirteen, or about twelve per cent. of the cases relapsed; one of the relapses was fatal (the case in which the autopsy was made). The longest case was fifty four days without a relapse, and the shortest a week.

There were seven cases of intestinal hemorrhage reported. One "smart pulmonary hemorrhage." One patient miscarried at about the third month with a severe hemorrhage. She recovered. Another case, pregnant about the same length of time, went safely through the fever without a miscarriage.

The average duration of the fever was about twenty-two days in all the cases reported.

The second week remission was generally very well marked. In several cases the temperature fell to 97° F. in the morning at or near the end of the second week, and very soon rose again.

Nine cases took the fever from drinking the milk once. In these the shortest period of incubation was fourteen days, and the longest twenty-seven. The average, 18.8 days.

The last case upon which I will comment is the 110th in the series, and is that of a nurse in the male ward of the Mountainside Hospital. She had charge of only one patient, who was very sick and died early in the epidemic. She was very much afraid of taking the fever, and was especially careful about washing her hands, etc., and was, moreover, naturally neat and careful in her habits. She fell sick with typhoid on May 9th. She had drunk H. T.'s milk on March 29th, or forty-one days before the fever appeared; whether she took the fever from her single patient by inhalation of the germs or otherwise, or whether in her case the incubation was almost six weeks, is an interesting problem. Personally, I incline to the latter opinion.

Only one other nurse is known to have contracted the fever. The case was said to have been a very mild one. Its cause has not as yet been fully investigated.

Of the total number of cases reported, 33 were treated by homœopathic practitioners, and their reports show a total mortality of 8, or twenty per cent. The number treated by the regular practitioners was 76, with a mortality of 6, or 7.8 per cent.

This notable disparity in results is similar to that reported by Dr. Benjamin, of Camden, and recorded in the "Transactions of the New Jersey State Medical Society for 1893," p. 37. Dr. Benjamin stated that the Philadelphia Homœopathic Hospital had reported a death rate of twenty four per cent. in enteric fever, and the Pennsylvania Hospital one of nine per cent. This was one of the higher rates for 1893, since the Cooper Hospital in Camden reported a two per cent. mortality, and another of the Philadelphia hospitals a six per cent. mortality.

My thanks are due to nearly every physician in Montclair and Bloomfield, and to Dr. Whitehorn, of Verona, for valuable aid in preparing this paper.

OBSERVATIONS ON NOSE BLEED AND ITS TREATMENT.[1]

By S. KOHN, M.D.,

NEW YORK.

THE purpose of this paper is to direct attention to the etiology of nose-bleed, and to describe some methods of treatment for which the claim of novelty may perhaps be asserted.

The subject is of fully as much interest to the general practitioner as to the specialist; its importance is attested by the fact that almost every writer on general medicine, from the times of Hippocrates and Galen down to the present, devotes space to its consideration; special articles which have attracted wide-spread notice, to mention only a few, have been written by Cloquet. Friedrich, Störck, Voltolini, Chiari, Bresgen. B. Fränkel, Krause, Duchek, Schech, Kiesselbach, Hartmann, Zuckerkandl, Mackenzie, Bosworth, and Solis Cohen.

E. C. Morgan, in Keating's Cyclopædia, "Diseases of Children," contributes a capital article on the subject; quite a complete *résumé* of the literature is to be found in Bresgen's "Handbuch der Krankheiten des Nasen, Mund, und Rachenhöhle," Wien, 1891.

Nose-bleed is met with under such a variety of conditions that it will be well to take a survey of its etiology before considering the treatment. Its causes may be classified under two headings: 1, Local; 2, Constitutional.

Local causes are, *A*: Traumatisms, which may be: *a*, operative, as for the removal of polypi, hypertrophies, tumors, exostoses, the correction or removal of septal deflection; *b*, blows and falls on the nose, with or without fracture of the nasal bones; *c*, habitual picking of the nose, frequently met with in children, not so frequently in adults; may or may not be due to deflected septum or spina, or septum over which the epithelium is thinned, and upon which crusts form; these are so firmly adherent that, to remove them, the finger nail is dug into the mucous membrane; a loss of substance and bleeding result; the frequent repetition of this procedure finally leads, in some cases, to perforation of the septum.

B. Congestions, active or passive. *Active congestion* is frequently the cause of recurring hemorrhage from the nose in children up to the age of puberty, without any appreciable lesion discoverable in the nasal mucous membrane; and seems to be due, primarily, to the active processes of growth and development at this age; and, secondarily, to the vascularity of the erectile tissue of the nose; about the age of puberty it seems to be more frequent in girls than boys, and is attributable to the establishment of the menstrual function and the developmental activity incidental thereto. Active congestion leading to hemorrhage may be caused by the inhalation of irritating vapors, powders, gases, etc.

The overheated and impure air of school-rooms frequently causes congestion of the nasal mucous membrane and bleeding, much to the schoolboy's delight, as it serves him as a pretext for escape from the poorly ventilated room into the pure air. Vicarious menstruation is recognized by the occurrence of the nose-bleed at the menstrual period. Cardiac hypertrophy may cause active congestion and consequent bleeding from the nose.

[1] Read at the January meeting of the Society of the Alumni of Charity Hospital.

Passive congestion of the nasal mucous membrane leading to bleeding may be produced by a multiplicity of causes; the bleeding is, in these cases, symptomatic; attention is called to the causes, for the purpose of showing the importance of making a thorough physical examination of every patient suffering from epistaxis.

Causes of Passive Congestion of the Nasal Mucous Membrane.—*a*, Valvular lesions of the heart, more or less uncompensated; *b*, diseases and degenerations of the heart-muscle; *c*, diseases of the lungs and pleuræ: chronic bronchitis, emphysema, tuberculosis, pleurisy in all its forms, empyema, whooping-cough; *d*, diseases of the liver, spleen, kidneys, suprarenal capsules; the diseases of the parenchymatous organs may produce nose-bleed by causing congestion, active or passive, or by bringing about such changes in the constitution of the blood, or in the walls of the blood-vessels, that diapedesis occurs, *i.e.*, tuberculosis, jaundice from an alcoholic or cirrhotic liver, Bright's disease; *e*, atheroma.

C. Growths, benign or malignant, adenoid vegetations, vascular polypi, sarcoma, carcinoma, angioma, caries, necrosis, ulcerations, syphilitic gummata, rhinoliths, which may for years erode the mucous membrane and cause recurrent bleedings; foreign bodies, introduced into the nose, such as shoe-buttons, peas, etc., which the young patient is usually afraid to mention, but which remain in the nose months, and in some cases years, causing recurrent bleedings.

Under the second general heading of the etiology, viz., Constitutional causes, are *a*, the continued fevers, typhus, typhoid, relapsing, and yellow fever; the malarial fevers; *b*, the exanthemata, measles, scarlatina, smallpox, in all their varying degrees of severity; *c*, septicæmia, diphtheria; *d*, gout, rheumatism; *e*, chlorosis, anæmia, simple or pernicious; *f*, hæmophila. Finally, mental emotions: fright, rage, may bring on an attack of nose-bleed; coitus, masturbation. Heredity may act as a predisposing cause. Senility sometimes predisposes to it.

It is thus seen that nose-bleed may be encountered under a great variety of conditions, at any time of life, in both sexes; that it may occur in the healthy and robust, or in the course of acute or chronic disease.

It frequently occurs without premonition, during the physician's visit perhaps, as in the course of typhoid fever; in this disease it has been considered by the older writers to be the critical bleeding; it may, however, be so copious as to endanger the life of the patient.

Or again, a patient is brought to the physician with a history of oft-repeated bleedings from the nose, more or less profuse, resulting in enfeeblement of the system; at the time of the visit, however, the patient has no bleeding. The bleeding usually is only from one nostril; it may, however, come from both; the amount of blood lost varies from a few drops to such a large quantity as to endanger the life of the patient.

Treatment.—In considering the treatment, in view of the etiology, it is proper to consider, first, prevention, and secondly, the means for causing the cessation of the bleeding.

Prevention.—In the case of a patient giving a history of repeated bleedings, without any sufficient exciting cause, a most searching examination of the nose and naso-pharynx is essential; if an erosion or varicosity be found, as it frequently is, on the lower anterior portion of the cartilaginous septum, this should first be dried with absorbent cotton, and then cauterized with a saturated solution of chromic acid, as advised by Bosworth and Bresgen; Chiari claims to have found such a lesion in 70 out of 81 cases of habitual nose bleed, and advises the galvano cautery beyond all other measures. The writer has seen the galvano cautery cause nose-bleed so frequently that he hesitates to recommend it, in these cases, to the general practitioner. Angiomatous growths have been the cause, in some cases, of such profuse and repeated hemorrhages, as to bring the patient to the verge of syncope; their radical destruction by the flat galvano-cautery is effectual in checking the recurrence of bleeding. Tumors, vascular polypi, adenoid vegetations, enlarged tonsils, if found in a patient suffering from habitual nose-bleed, must be removed.

If the child be a "mouth-breather," attention should be directed to the naso-pharynx and the adenoids, which in all probability will be found removed.

Under prevention, the treatment of the general conditions named under etiology must be considered, viz., anæmia, chlorosis, hæmophilia, diseases of the heart, lungs, pleuræ, parenchymatous organs, etc., into which it is not the province of the writer to enter.

It is mentioned for the purpose of emphasizing the necessity for a thorough physical examination of every patient suffering from nose-bleed. Suffice it to say, that if habitual constipation exist, the bowels should be regulated by mild salines, that in an enfeebled state of the system, iron, quinine, strychnine, the mineral acids, cod-liver oil, may be administered according to the indications; fresh air, exercise in the open air, and bathing, either fresh or salt water, are to be commended in patients who are debilitated by repeated bleedings.

As has been mentioned under the etiology, there are still left, however, some cases in which the bleeding occurs spontaneously, without any lesion being discoverable. These occur more especially in growing children, who otherwise are in good health. Ergot has been recommended as a preventive in these cases by Morell Mackenzie. The writer has found in the fluid extract of hydrastis canadensis a sovereign remedy in these cases; he has had occasion to use it in a large number of cases of nose-bleed in the German Poliklinik, and has found it efficacious in preventing a recurrence in a large majority of cases. It is administered internally, in ten-drop doses in water, every two or three hours. This apparently simple treatment can be recommended with confidence in the cases above mentioned. The alkaloid hydrastinin, in the form of a hydrochlorate, has been put up in tablet form in one-twentieth-grain doses, and in combination with ergotin, by Mr. M. J. Breitenbach, of this city, and is a most elegant method of dispensing the drug. The hydrastis is prescribed, be it understood, as a preventive, for the patient who at the time of his visit is not bleeding from the nose, but who gives a history of repeated bleedings. A five per cent. solution of the fluid extract of hydrastis in water may be used as a spray for the nose; it may also be used with liquid vaseline, albolene, or kindred preparations, as a spray or brushed into the nose. The drug seems to "tone" the mucous membrane; and by reason of its containing a bitter principle it has, when taken internally, a beneficial effect on the stomach, as is attested by the improved appetite following its use; its only drawback is, that it has a tendency to cause constipation, but this may be combated by mild salines.

The thorough examination of the nose and naso-pharynx for a local lesion to account for the bleeding is not the less necessary because of the use of hydrastis, or any other remedy which may produce a cessation of the bleeding for the time being; for if an erosion or vascular growth be the source of the hemorrhage, the only rational course is to attack it locally. It is not always possible to find such a lesion, nor have we at all times the instruments with us for making a thorough examination; in these instances, the fluid extract of hydrastis will be found a most reliable remedy temporarily.

Under the heading of prevention should be considered also the general laws of hygiene—pure air in school- and sleeping-rooms, bathing, assimilable food, etc.—to which it is unnecessary to call your attention.

So many different methods of checking an attack of nose-bleed have been recommended, that a review of them will be in place before the writer describes the simple procedure which he has in most cases found satisfactory. The various methods of treatment which have been recommended may be divided into, 1, non-medicinal; and 2, medicinal.

Non medicinal methods are: 1. External compression

upon the bleeding nostril, either by the fingers, iced cloths, ice-bags, or ice. 2. The hot nasal douche, the water having a temperature of 90° F., injected so long until it emerges from the non bleeding nostril unmixed with blood. 3. Ice in the mouth; cold cloths, ice, cold metals applied to the spine; immersing the scrotum in iced water. 4. Chapman's bags, containing water at a temperature of 105° F. to the spine. 5. Cups or blisters to the hepatic or renal regions; mustard plasters to any part of the body or extremities, for producing counter-irritation.

Medicinal Treatment—1. By astringents, in form of powder, insufflated, viz., tannin and alum; or in liquid form or solution, applied with brush or by means of the spray, viz., the preparations of iron, the muriated tincture, Monsel's solution, diluted with glycerine; glycerite of tannin, solutions of sulphate of zinc, acetate of lead, sulphate of copper, kino, catechu. 2. Escharotics and caustics; in order to properly apply these, the blood must be rapidly touched off with pledgets of absorbent cotton or lint, so as to expose the bleeding point to view; this may then be touched with a saturated solution of chromic acid, a sixty per cent. solution of nitrate of silver, or a crystal of this salt may be fused on a silver probe and be thus applied; nitric acid (which must be used with great care), the galvano-cautery.

Finally, *internal compression* has been recommended: 1. By means of absorbent cotton pledgets, introduced into the nostril until the bleeding ceases; the number of pledgets should be counted, so that none are left behind when they are removed; or they may be connected by a strong thread, which simplifies their removal; they may be saturated with astringents in solution, *i.e.*, tannin, acetate of lead, sulphate of copper, etc. 2. By means of long, narrow strips of iodoform gauze, gently introduced into the bleeding nostril, until this is entirely occluded, leaving the end of each strip visible at the anterior nares. 3. By means of small rubber bags, on the principle of Barnes's dilators, introduced into the nostril empty, and then inflated with air or filled with cold water. Finally, plugging of the posterior nares with Bellocq's cannula; this should be the *dernier ressort*, and under no circumstances should be tried unless all other means fail, as it is itself not devoid of danger; cases of erysipelas, gangrene, sepsis, and even tetanus, have been reported as following its use.

The writer recalls the case of a man whom he saw one week after the posterior nares had been plugged; the physician who had introduced the tampon could not remove it, it had become so tightly wedged and was so fetid that the patient suffered from infection, and said he preferred the bleeding to the treatment. It was with considerable difficulty that the plug was finally removed.

A twenty per cent. solution of antipyrine, a ten per cent. solution of cocaine, applied by means of cotton pledgets, which are allowed to remain *in situ*, have also been recommended as reliable remedies to stop the bleeding.

The varied methods above mentioned certainly form an imposing array.

It has seemed to the writer that the simple rules for the stoppage of capillary hemorrhage are applicable to these cases; the object is, as in any hemorrhage, to secure coagulation at the point of bleeding, and to keep the clot in place.

The first rule, therefore, is to place the patient, and more especially the bleeding part, at rest; nervousness or fright should be quicted with assurances that there is absolutely no danger; the patient should sit upright in a chair, the head thrown slightly backward; all bands about the neck should be loosened, in order that the circulation may be unimpeded; the patient should then open the mouth as widely as possible, and should breathe through the mouth only; breathing through the nose should be entirely suspended until bleeding ceases, and should be superseded by oral breathing; blowing the nose, hawking, and spitting must be strictly interdicted; we all know how prone patients suffering from nose-bleed are to do these things. In following the instructions thus far given, the interior of the nose is placed at rest, and the first indication is fulfilled; whereas, if the patient snuff up cold water, wipe or blow the nose, he displaces clots and favors the continuance of the hemorrhage.

The second rule is to tell the patient, his mouth being kept wide open, to breathe more deeply and more rapidly than he normally does; the respiration may be increased to thirty per minute; the immediate effect of this increased oxygen supply is to increase the force and frequency of the heart's action, and presumably to increase the amount of blood in the pulmonic circulation at the expense of the cerebral; whether it be due to the more thorough equalization of the blood supply to the body and head, or to the increased muscular action incident to the increased respiratory effort, it has seemed to the writer that the nasal mucous membrane is depleted to some extent by this procedure.

The use of opium and digitalis in hæmoptysis is to a certain extent attended by the same result here obtained, viz., a more powerful contraction of the heart-muscle.

As soon as the patient tires of the rapid breathing—which he does very soon, perhaps after thirty respirations—he may breathe normally for a few moments, when, if the bleeding has not ceased, he is told to breathe rapidly again; the mouth is to be kept open constantly, and any blood flowing into the pharynx is to be swallowed.

The fact that blood is withdrawn from the brain by this procedure is attested, in the opinion of the writer, by the dizziness which most patients experience when they resort to it, and by the pallor which the face assumes; the same symptoms have been noted by every physician during prolonged auscultatory examinations of the chest; some patients are apt to faint during such examinations; it seems to the writer that a temporary anæmia of the brain is the cause of these phenomena.

The final rule is, to tell the patient to enunciate the broad vowel "A" with each expiration; the soft palate is thus brought in contact with the posterior wall of the pharynx during each expiration, the posterior nares are separated from the pharynx, and the blood is prevented from flowing into the œsophagus during the expiratory periods.

The three principal factors in this simple method of arresting nose-bleed are, first: to place the nose at rest by suspending breathing through it; second: rapid and profound respiration, acting as a respiratory and cardiac stimulant, more equally distributing the blood throughout the systemic and pulmonary circulation by abstracting it from the head; and third: the occlusion of the posterior nares during the entire expiratory period by the intonation of the broad vowel "A" during expiration.

This method is so easily applicable that after every operation in the nose attended by bleeding the writer makes use of it; it is so much cleaner, and simpler, after the snaring of a vascular polyp or the removal of an exostosis, to make use of this procedure than to apply astringents that interfere with the field of operation, that it is invariably tried by the writer before any other means are applied. Of course it may in some cases of severe bleeding from a larger vessel fail; in these I would then try first the insufflation of tannin; and if this fail the tamponing of the nostril with long narrow strips of iodoform gauze, dipped in the glycerite of tannin, with the ends hanging out of the nostril. It is needless to dwell on the advantages of a method of arresting nasal hemorrhage in which no drugs or instruments of any kind are necessary. A few weeks ago I had occasion to see a severe attack of nose bleed occur during the course of typhoid fever; had I been compelled to send to my office for instruments, drugs, etc., the patient might have succumbed in the meantime; the simple method above described had the effect of arresting the bleeding at once.

Astringents in reality cannot cope with a severe nasal

hemorrhage, as the clot formed by most of them, especially the preparations of iron, does not extend down to the bleeding point; they induce superficial coagulation, and some of them produce such a dirty, grumous compound that the field is obscured, and even though the bleeding stop the patient feels extremely uncomfortable.

In children the aversion to all instruments in the doctor's hands is so pronounced that it is well-nigh impossible to use the nasal speculum, not to speak of the galvano cautery, during an attack of nose-bleed; the method recommends itself for children.

Summary.—Prevention: 1. Improve the general health of the patient by following the causal indications; 2, treat local conditions, "lege artis;" 3, administer the fluid extract of hydrastis canadensis as a specific.

Arrest of the nose-bleed, three methods of treatment: 1. By rapid and deep-breathing through the open mouth, at the same time enunciating the broad vowel "A" with each expiration; 2, find bleeding point, touch with chromic acid, nitrate of silver, galvano-cautery; 3, tampon the bleeding nostril with strips of iodoform gauze, dipped in astringents in suspension or solution.

Every method of treatment described above, excepting that by hydrastis canadensis and rapid breathing, has been advocated in published papers by different writers, some of whose names were mentioned in the first part of this paper.

MEDICAL WITNESSES, FROM A PHYSICIAN'S STAND-POINT.[1]

By HUBBARD W. MITCHELL, M.D.,

NEW YORK.

Much has been said and written during the past few years upon the subject of medical witnesses in courts of law. This subject has been the theme of many elaborate papers in which are set forth, sometimes in very pointed and uncomplimentary terms, the unsatisfactory character of the testimony of medical witnesses in courts of justice. Most, if not all, of these papers have been written by members of the legal profession, and none, so far as I know, by physicians. Both the bench and the bar have united in the opinion that medical men, when called to the witness chair, have proved contradictory and generally unsatisfactory. The bench, especially, has declared that it could gain little or no enlightenment from the testimony offered by the medical experts, that their opinions were conflicting, and threw little or no light upon the subject in which they testified. The bar has been equally emphatic in expressing a like opinion, and stating that medical witnesses were biased and partisan, confusing and contradictory. This feeling has increased to such a degree that both the judiciary and the legal profession look with unfavorable eyes upon the medical expert in the witness chair. They have not given him that degree of respect which his professional attainments deserve, and have sometimes withheld it altogether, and if his testimony can be dispensed with in any given trial, he is not invited to give it.

The question naturally arises, what is the reason for this condition of things, why are medical men unsatisfactory in the witness chair, and why is their testimony held in such light esteem—an esteem which is justly due them? The causes are many and difficult of explanation—a few only of these can be touched upon in this paper.

It is true that the profession of law is a high and most honorable one. Our courts of justice are usually pure and above reproach, and in the trial of causes they seek to obtain the exact truth, that they may base an opinion upon which to render a fair and impartial judgment. We can justly boast that there exists a better and purer and more competent judiciary in this country than perhaps in any other. Justice is within the reach of all, and the law extends its strong and protecting arm about the weak, and all men are equal before it. This is the ideal, and it is also generally the fact; but in some cases a different state of things actually exists.

Judges are men, they are human, with the idiosyncrasies, the weaknesses, and the prejudices of other men, and while they mean to be fair generally, and usually are so, yet they are not always above the influences which sway other men; and it sometimes happens that judges are selected through political influence, and the same influence that elevated them to the bench is sometimes exerted to modify or change their decisions. We have had many notable instances of this in the past in our own country, and cases of injustice in other countries have been monstrous in the history of law. It has been a reproach in this and other countries that law is for the rich and not for the poor, and it has been said many times that the rich man cannot be convicted of crime. Shakespeare was aware of this fact when he said, "In the corrupted currents of this world, offence's gilded hand may shove by justice, and oft 'tis seen the wicked prize itself buys out the law."

In modern times the impartiality of the judiciary and its honorable desire to render purer and more strict justice to all, is a gratifying sign of the advancement of higher and better ideas.

When a physician is called to the witness chair the court usually treats him with courtesy and consideration. It recognizes the honorable and learned nature of the profession to which he belongs, and accords him a proper degree of respect.

Not so always the bar.

In a given suit of law where medical questions are involved, the plaintiff calls to his side medical men whom he thinks will testify favorably to him, and the defendant does precisely the same thing. If the medical witness for the plaintiff gives testimony which is damaging to the defendant, the counsel for the defendant proceeds to cross examine him, and sometimes with a license that is truly appalling. The medical witness in such a case is often treated with extreme severity and indignity, and no effort is spared to either confuse him, or to neutralize or render ridiculous the effects of his testimony. This is sometimes so irritating, discourteous, and unnecessary, that medical men hesitate before placing themselves in such a position.

The differences of opinion among medical men are much less, when carefully and impartially viewed, than would at first seem. Medicine is not an exact science. It is a high and honorable art, and sometimes it happens that a variety of methods of treatment answer equally well in the same case; and when physicians are testifying in the witness chair they may give different views upon the same point, and yet the differences are not vital or important in a medical point of view. This is one reason why medical men seem to differ in the witness chair. Another is that where several witnesses are called, one may see the subject very clearly and testify accordingly, while the others do not grasp the situation as completely, and consequently give their testimony in an uncertain and perhaps contradictory way. Outside of a court of law this would not be regarded very seriously, because the better and clearer opinions would prevail, but within a court of law the effect produced is very different.

It is unfortunately true, and greatly to be deplored, that medical men sometimes become partisans in the case to which they are called. Nothing could be more detrimental than this, for it is not the province of the physician to become a partisan in the case where he is giving medical evidence. He should give his testimony in a clear, straightforward, and conscientious way, confining himself strictly to the medical aspect of the case, and give these facts clearly and plainly, without any regard whatever to their effect upon the case at issue. Neither judges nor lawyers ask him or expect him to give a medical homily, nor do they require him in any way to become interested in the case; neither should he pose as an expert, but simply as a learned and dignified physician,

[1] Read before the Medico-Legal Society, May 9, 1894.

giving his opinions to the best of his knowledge and belief, maintaining his dignity at all times, strengthening his opinions with sound learning, and conducting himself generally as an earnest and honest exponent of facts within his knowledge and belief. The outcome of the case is beyond his province, and should in nowise interest him. No one can reprobate this partisan tendency more than myself.

Medical men are, as a rule, honest in their opinions, earnest in their desire to tell the exact truth, and to arrive at a clear and just understanding of the case. They are, as a class, self sacrificing, and think first of the good they can accomplish in the case before them, and I believe it is strictly true to say that when they go upon the witness stand they have a strong desire to tell the truth in the best possible way and without partisanship or bias.

Physicians are easy men to deal with, if proper respect is shown them as professional men, and when a due regard is given to their opinions, which they strive to tell honestly; but when words are sought to be put into their mouths which they do not wish or intend, or when they feel themselves instructed, or when they find themselves mercilessly handled by the cross examiner, simply because they tell an unpalatable truth, they justly and properly resent it. Lawyers do not always comprehend the fine and delicate reasoning physicians are compelled to employ in the difficult problems presented to them in their severe professional work, and when this method of reasoning is made use of on the witness stand, it is not understood by the opposing counsel, and his inability to understand the medical witness is made the theme of a rebuke to medical witnesses generally.

It is often true that the counsel on one side does not always want the truth, and if the defendant or plaintiff is in the wrong, he certainly does not want the truth, if that truth will injure his cause, and hence he will seek to find a physician who will give an opinion favorable to himself.

Another reason why medical men differ is, that the plaintiff will give his medical witness his own view of the case, and the defendant will give his medical witness his own view of the case, and the physician goes upon the stand with only a part of the truth in his possession. This must of necessity lead to a conflict of opinion among the medical witnesses. As an instance of the fact where the prosecutor for the people did not want the exact truth, I will cite a few facts in the case of Brown *vs.* Brown, tried at Long Island City four years ago.

The defendant was charged with an attempt at manslaughter. The plaintiff testified that he had been knocked down and beaten with a heavy monkey-wrench in the hands of the defendant. The medical witness for the plaintiff testified that he had found the plaintiff lying upon the floor with blood pouring from deep scalp wounds, which he had sutured and dressed, and said the plaintiff was exsanguinated from loss of blood. I was called for the defence, and after listening to the evidence, testified that no scalp wound had been inflicted, that no blow with a monkey-wrench could have been struck, that the plaintiff could not have lost an ounce of blood, and that no suturing had taken place. These were the facts which were afterward proven, and my testimony was diametrically opposite to that of the physician called for the plaintiff. The prosecutor had proven his facts to his own satisfaction before I was called to the stand, and my testimony completely upset his case. I was subjected to a cross-examination which for ungentlemanliness, discourtesy, and even brutality, can hardly be equalled. The prosecutor sought to put words in my mouth which I did not mean, and attempted, by ways which seemed to me unprofessional at least, to make my opinion appear ridiculous in the eyes of the court and jury.

It is this kind of treatment, to which a physician is so often subjected, that makes him unwilling to go upon the witness stand. In cases like this I can hardly charge my professional brethren with wilful dishonesty, and yet truth constrains me to say that, in rare cases, medical men do sometimes appear to distort facts in a most unaccountable manner. It may be from a misapprehension of the case, or from ignorance of all the facts, or from a partisan desire to help their own side, but such testimony brings contempt upon medical witnesses, and lowers the respect in which they should be held.

It is sometimes true that, when physicians become successful in the practice of their profession, either through their own real abilities or from extraneous causes, the success they attain occasionally leads them to become arrogant, and this arrogance is sometimes unfortunately shown upon the witness stand. Such men, it must be admitted, are narrow minded, and it is this class of men whose conceits lead them to contradictions which incur the unfriendly criticism of both bench and bar. When men of this character are called to testify in important suits at law, their disagreements with their professional brethren have been deplored by both judges and counsel. Such men are, happily, few, but sufficiently numerous, perhaps, to bring upon medical witnesses the unmerited and unjust criticisms to which we refer.

The question naturally arises, is there a remedy for this condition of things? Many suggestions have been made and many remedies proposed; some of them are good, and some are impracticable and inadequate. It is sometimes easier to point out an evil than to suggest a remedy for it.

Medical witnesses are a somewhat recent institution, and medical experts still more so, and the evils resulting from the conflict of opinion among them are, perhaps, to be expected until a wider range of experience enables them to correct their errors.

As stated above, medical men are, as a class, honest and conscientious, and they desire to give fair and unprejudiced opinions; and it seems to me that a better conditions of things could be obtained in any suit at law where medical witnesses are called, either by the plaintiff or the defendant, if these witnesses could be brought together and the case explained to them before the trial began. They would then be enabled to give their opinion with little contradiction and without partisanship, and if the medical witness, after he has been selected, either by the plaintiff or defendant, could be accepted by the court and placed under its sole control, he would then have removed from him any influence that could be brought to bear to make him a partisan in the case, and he could then give his opinion fully and more freely, without regard to its effect upon the case itself. He should remember that his testimony is medical testimony, purely and simply, and nothing else, and its effect upon the case at issue should not enter at all into his calculation. He should not be made to feel that he is to give testimony to help one side or hurt the other, but he ought clearly to understand that what he says is the plain and simple truth, upon the medical aspect of the case only. Its consequences, he must clearly understand, are beyond his province. He should not feel that he is taking sides, or is in anywise partisan, but ought to appreciate the fact that he is under the control of the court and under its protection also, and his testimony is purely professional, and he should in nowise become interested in its legal aspects. When the physician has been selected by either side as a witness, he ought to be allowed to confer with the physician upon the other side in the case, have all the facts explained to him, and then, when he goes upon the stand, let him give these facts in a plain, concise, professional, and dignified way; and it would be found that much, and perhaps all, of the contradiction and irritation and unsatisfactoriness of medical witnesses, so loudly and deeply deplored by bench and bar, could be very greatly averted.

Let the lawyers also understand that medical evidence is often a delicate matter, that its conclusions are reached only after a long process of difficult, and in many cases obscure, reasoning; that it is the result of arduous experience, but given nearly always freely and with honesty of purpose; and let them avoid undignified, unnecessary,

and discourteous cross-examinations, and they will find that much of the friction they so strongly decry will not be engendered.

MODERN ELECTRO-THERAPEUTICS: FROM THE ELECTRICAL STAND-POINT.

By H. NEWMAN LAWRENCE,

NEW YORK.

MEMBER OF THE INSTITUTE OF ELECTRICAL ENGINEERS, ENGLAND; AND FELLOW OF THE AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION.

Electro-therapeutics has now come to be regarded as a distinct branch of applied electricity—a valuable member of that numerous family classified under the head of "Electricity in the Service of Man." As such it naturally possesses much interest for the electrician as well as for the physician. This was not always the case, for the problems connected with other branches of applied electricity are so numerous and so absorbing that the electrical profession overlooked, or at best looked slightingly at, the efforts made by some physicians, whose *bona fides* could not be doubted, to build up a sound system of electro-therapeutics.

Times have changed, however; the science of electro-therapeutics has won for itself the respect of the electrical profession, and the electrical journals frequently publish articles and papers connected with it. Other evidence of the status of electro-therapeutics may be found in the attitude of the leading medical journals. They frequently refer to it, and mark with strong approval all signs of increased attention to the physics of the subject.

One reason for this increased activity in matters electro-therapeutical may perhaps be found in the gradual awakening of the medical profession to the fact that they, as well as the general public, are distinct sufferers through the prevalence of numerous quack appliances. These appliances, though generally absolutely devoid of all things electrical except the name, and applied by people entirely ignorant of pathology and physiology, are foisted upon a credulous public to an enormous extent, so that large sums of money are thereby diverted from their legitimate destination, viz., the pockets of the regular physicians. Other reasons there are, not the least of which may be the present rage for all things electrical or supposed to be electrical. Be that as it may, there can be no doubt that much activity does exist on this matter, and also that America is well to the front in all the recent developments.

It may therefore be well to call attention to certain difficulties which beset the electro-therapist, and to indicate matters which appear to the physicist as possible hindrances to the true development of electro-therapeutics. If the methods by which electricity is applied to the human body for the cure and relief of disease be not capable of exactness and accuracy—in other words, if they be not scientific—they are worth nothing, and their adoption and practice would be a disgrace to the medical profession. Of course, everything of the kind must have time for growth, scientific accuracy cannot be attained in one stride; but, certainly, accuracy should be aimed at and striven for with that persistent earnestness which characterizes all true scientists. The tone of nearly all the modern writers on this subject is most encouraging in this direction, but personal observation goes to show that for some reason or other this desirable accuracy is sometimes overlooked by many of the medical profession. A few months ago one of the leading electrical journals,[1] in England, in an article dealing with the uncertainty of results in electrical treatment said:

"The human body is so complicated and individualized a structure that it is hard to see how we can be quite certain of the results of any form of treatment upon it. Besides, when other things are favorable the faith factor may entirely upset all calculations, for while in some cases it helps, or perhaps entirely performs the cure, in others it may retard, or even prevent it. Other forms of treatment have their uncertainties as well as the electrical, and not always, perhaps, with so good a reason. The main cause of uncertain results is to be found not in the current itself, but in the way it is administered. . . . No measurement, no knowledge of the functions of currents, no idea of the resistance of the body, no attention paid to surface area or to current density, and often even the most rudimentary knowledge of matters electrical entirely absent. If the current be not measured, the dose may be too weak or too strong. Of course it may be just right, but the chances are two to one that it is not. Too great chemical action may easily be not only useless, but distinctly harmful. Nerve and muscle stimulation are valuable to a certain point, but is it not possible to over-stimulate, and so turn good into evil? Who can properly select the form of current in any case when ignorant of the functions of such currents? How can any current be properly applied when nothing is known of the resistance of the body which it is desired to influence, or how to direct the current so that the parts treated shall be really affected by its flow? And, lastly, how, in the name of common-sense, can good results be expected, or serious injury avoided, when an agent so potent for good and evil is applied to the body by persons entirely innocent of the most elementary knowledge of electricity?"

The position was then summarized as follows: "1. On the evidence of some of the greatest medical scientists, electricity is a most valuable curative agent in very many of the known diseases of man. 2. The opinion of these men has been formed, to a large extent, upon the results of loose and empirical methods of application. 3. Enough is now known of the measurement and control of electrical energy to render more accurate and reliable work easy. Therefore it is reasonable to expect that more accurate methods in electro-therapeutics would produce better results."

Unfortunately one of the great difficulties that medical men have to contend with is that a more accurate knowledge of the measurement and control of electrical energy is not easy for them to obtain. Their ordinary course of preparation for their profession does not include it, and, when once launched on the busy round of daily practice, they have little time or opportunity to devote to what is, in itself, a distinct study. Improved apparatus and reliable measuring instruments have done something to remedy this defect, but these are of little use without an accompanying knowledge of the properties of currents, the laws which govern them, and their special functions with reference to the human body. Too much stress can hardly be laid on this point, for a physician attempting to treat disease by electricity without such knowledge would be in a position similar to that of one attempting to treat by drugs without any knowledge of chemistry. His methods must be all chance and guess-work. In saying this the existence of many excellent text-books is not overlooked, but the blind following of text-book instructions can, at best, be but a rule of thumb proceeding, and, seeing the powerful nature of the agent dealt with, may easily result in serious disaster.

If, then, electro-therapeutics is to take its place as an exact science, as it even now is in the hands of some, this point must not be lost sight of; the subject is at least as complicated as any other branch of applied electricity, and can never hold its place without a due attention to its physics as well as to its therapeutics.

A most interesting effort to overcome this difficulty in America has recently been made at the University of Michigan by the establishment of an electro-therapeutical laboratory in connection with its medical department. Here opportunity is given the student "to become personally familiar with the appliances used in electro therapeutics by constructing them out of the raw material, studying their modes of generating, modifying, and controlling electricity and observing the physiological and therapeutical effects they produce." To the

[1] Electrical Review, London.

electrical engineer this seems a most commendable step in the right direction, and, moreover, an example which New York, the metropolis of the United States, might follow with advantage to its medical profession and with honor to itself.

Another difficulty which the electro-therapist has to face is in connection with the selection of apparatus and with its management when selected. The forms of current credited with special powers for special cases are by no means few, and the number of generators of one type or another is legion. Great care therefore is necessary in the selection of apparatus suitable for the particular work the physician desires to undertake. To a large number portability of the apparatus is an all-important feature, to others permanent installations are of more use. The conditions of treatment are such that a battery best suited to one class of cases may be of no use at all for other cases. For instance, if a country physician desires to treat general nervous conditions by means of percutaneous applications he requires a battery of many cells to overcome the high resistance of the body, but they need not be of large size because the current used would never exceed a few milliampères. If he wants to treat gynecological cases he must have larger cells, as more current is generally required for such cases. Or again, should his requirements run in the direction of cautery work, his cells need only be few, but they must be of great capacity, for while the resistance to be dealt with is very low, the current required to heat a cautère is often a hundred times greater than that needed for the first class of cases. The makers of electro-medical apparatus, are, for the most part, honorable men, and do their best to supply their customers with apparatus suited to their needs; but still their business is to sell apparatus, and they are sufficiently human to endeavor to sell that which brings in the most profit to themselves. It cannot be well for the physician to be entirely at the mercy of apparatus-makers, either as regards selection of goods or repairs; but unless he himself knows exactly what he wants and how to correct, at least, simple faults when they appear, he is hardly as independent as he should be, especially when, through living in the country, he has to negotiate by correspondence.

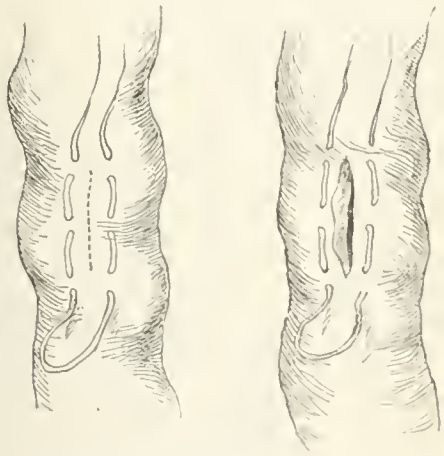
These form some of the difficulties and dangers to which modern electro therapeutics is exposed, but they really form only the reverse side of the position. The obverse is bright and its beauties clearly marked. Eminent scientists lend their direct aid to its developments, and research work of the highest order is being carried on. Edison gives his attention to electrical osmosis as applied in cataphoric medication; Tesla startles the world with physiological phenomena connected with currents of high potential and frequency; D'Arsonval shows that these Teslaic currents may be advantageously used in therapeutics; Gautier and Lerat find new virtues in sinusoidal currents, and Dr. W. J. Morton sets forth the theory of a possible electric polarity of metabolism which, if it stands the test of practice, will place electro-therapeutics in the highest rank of the exact sciences.

A New Medical Grade.—Sir B. Ward Richardson, in the last number of the *Asclepiad*, advocates the recognition, examination, and registration of counter-prescribers. He says, first, that they are honest practitioners in their way; second, they are useful to the public under certain circumstances; third, whether they are or not, they are certain to continue to exist, because it would be almost impossible to put in action any law for their suppression, if it were desirable to do so. But he would not tolerate the counter-prescribers' invasion of visiting practice under any circumstances.

An Impassioned Kiss.—A young woman in New Jersey was kissed so ardently by her lover that the gold filling dropped out of a tooth. He was disinclined to pay for repairing the damage and she has accordingly sued him, and the engagement to marry is broken off.

INTESTINAL APPROXIMATION: PATHOLOGICAL HISTOLOGY OF REUNION, AND STATISTICAL ANALYSIS.[1]

By J. B. MURPHY, M.D.,



PROFESSOR OF SURGERY AND CLINICAL SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO; PROFESSOR OF SURGERY, POST GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO COOK COUNTY HOSPITAL; ATTENDING SURGEON TO ALEXANDER BROTHERS' HOSPITAL; CONSULTING SURGEON TO HOSPITAL FOR CRIPPLED CHILDREN, FELLOW OF ACADEMY OF MEDICINE, CHICAGO, ETC.

APPENDIX.

I HAVE received so many letters within the last few months regarding the technique of the insertion of the button, that I deem it necessary to append it in detail.

Technique of Insertion.—1. *Cholecystoenterostomy.*—An incision is made from the edge of the ribs, two inches to the right of and parallel to the median line, extending downward three inches. The gall-bladder and duodenum are drawn into the wound; a needle with fifteen inches of silk is inserted in the duodenum directly opposite the mesentery and at a point near the head of the pancreas; a stitch is taken through the entire wall of the bowel one-third the length of the incision to be made; the needle is again inserted one-third the length of the incision from its outlet, in a line with the first and embracing the same amount of tissue as the first. A loop three inches long is held here and the needle is inserted in a similar manner, making two stitches parallel to the first in the reverse direction and one-fourth of an inch from it, coming out at a point near the original insertion of the needle (Fig. 2). This forms the running thread, which when tightened draws the incised edge of the bowel within the cup of the button.

FIGS. 2 and 3.—Showing Running Thread Before and After Incision in Bowel.

A similar running thread is inserted in the gall-bladder; an incision is now made in the intestine two thirds the length of the diameter of the button to be used; avoid cutting the running thread when making the incision. The button is slipped in, the running thread tied firmly around the central cylinder; an assistant holds the button in position with the hæmostatic forceps. An incision is now made in the gall-bladder the same length as the one in the intestine between the rows of sutures. The gall-stones and fluid contents of the gall-bladder are removed, the button inserted, and the running thread tied. The forceps are then removed, the button is held between the fingers, as shown in Fig. 4, and slowly pressed together. Note that the edge of the wound comes entirely within the clasp of the button before it is completely closed. A sufficient degree of pressure must be used to bring the serous surfaces of the gall-bladder and intestines firmly in contact and compress the tissues. The elastic pressure of the spring cup of the button produces a pressure atrophy of the tissues embraced by it and leaves an opening as large as the button. When the button is liberated it passes on through the bowel.

[1] Read by invitation before the New York Academy of Medicine, December 7, 1893.

2. *Pylorectomy.*—Having drawn the pylorus into the abdominal wound ligate the greater and lesser omenta and cut them off; then make a circular incision on a groove director with the scissors, cutting through the muscular and serous coats down to the mucous coat, completely around the stomach where it is to be excised; then denude the mucous membrane of its muscular and serous coats for half an inch in the direction of the fundus; excise the mucous membrane at this point; close the mucous membrane with continuous catgut suture, and over this the serous and muscular coats with interrupted silk suture. The end of the stomach is now completely closed. Excise the duodenum an inch and a half below the pylorus, insert a running thread as described under the head of end-to-end approximation, to follow; place the male half of the button in position. The female half of the button is inserted in the posterior wall of the stomach two inches from the line of suture, in the same manner as it is inserted in the gall-bladder. The forceps are removed and the button pressed together. The end of the duodenum is thus joined to the posterior wall of the stomach. The button liberates itself and passes on through the bowel.

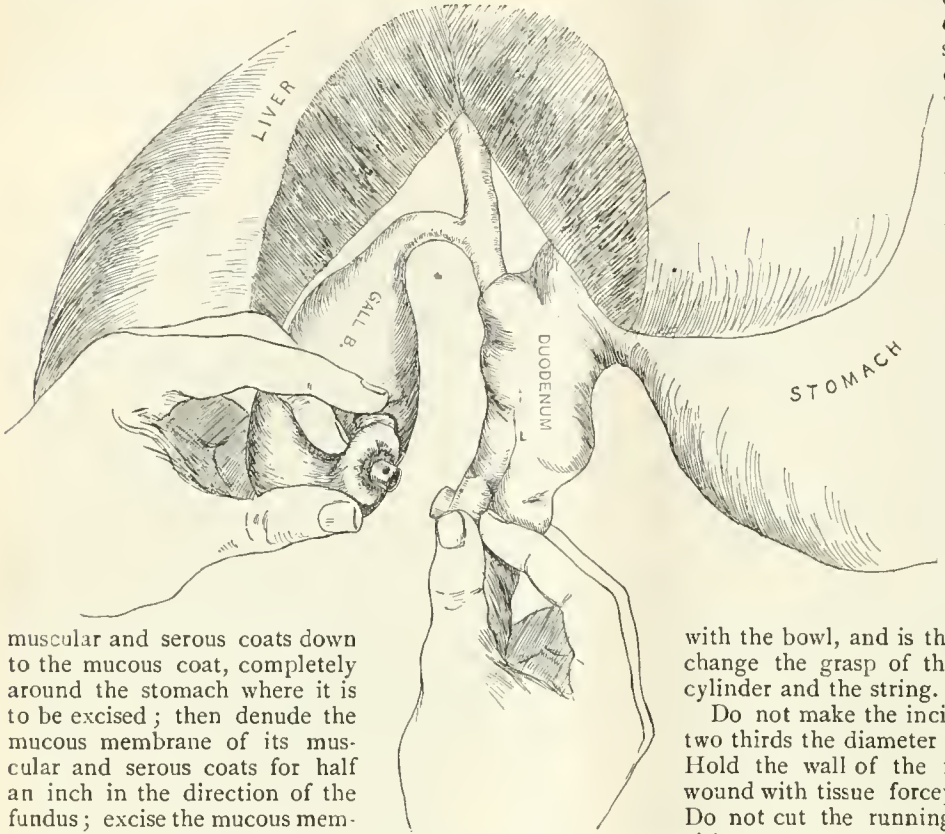

Fig. 4.—Button as Held when Pressed Together, Performing Cholecystoenterostomy.

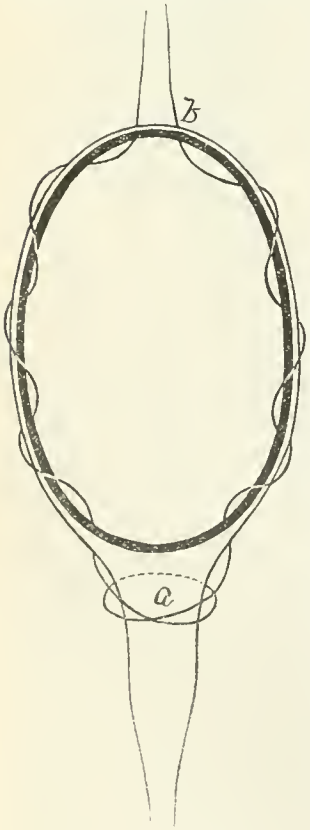

Fig. 5.—Manner of Inserting Running Thread in End of Bowel.

3. *End-to-end Approximation.*—The intestine is cleared of its contents and the intestinal compression clamps placed in position; the mesentery of portion to be excised ligated; portion of intestine excised; running thread placed in position by a top stitch along the incised edge, beginning opposite the mesentery and continuing down to the mesentery; one return over-stitch is taken at the mesentery and then continue the top stitch up the opposite side to the starting-point, as in Fig. 5; this constitutes the "puckering-string," and when tied around the stem of the button, which is then inserted, draws the cut edge within its clasp. Particular attention should be given to the return over-stitch at the mesentery, so that both layers of the peritoneum overlap. The other half of the button is inserted in the same manner and is then pressed together. Close opening in mesentery with one or two sutures.

4. *End-to-side Approximation.*—Half of the button is inserted in the same manner as for end to end approximation and the other half the same as for lateral approximation and is pressed together.

When inserting the half of the button to which the circular compression-ring is attached, compress the ring to the edge of the bowl and grasp both with the forceps. This holds the ring down to a level with the bowl, and is then more easily inserted; then change the grasp of the forceps to the edge of the cylinder and the string.

Do not make the incision too long, not more than two thirds the diameter of the button; it will stretch. Hold the wall of the intestine at each end of the wound with tissue forceps while inserting the button. Do not cut the running thread when making the incision.

Do not inclose too much tissue in the suture. When closing the button be sure that the incised edge is always within the clasp of the button. Bear in mind that the button is not indestructible. Do not use a Lembert suture with the button; it is useless and positively dangerous. It is not necessary to abrade the peritoneum.

Button.—I have seen a number of imperfect buttons on the market, so they should be carefully examined before purchased. The spring should always be made of brass, steel will rust. The edge of the cup should never be sharp, but should have a line of surface.

The Physical Measurements of New York Girls.—The *Gymnasium* publishes the following as the average measurement of 325 New York girls whose average age was 19.4 years:

Weight	117.5 pounds		Inches
	Inches	Girth: Hips	35.2
Height	64.0	Upper arm	9.5
Girth: Chest	29.2	Forearm	8.7
Chest, full	31.2	Depth: Chest	5 9
Ninth rib	26.2	Abdomen	6.1
Ninth rib, full	27.9	Breadth: Shoulders	12.5
Waist	22.7	Hips	13.0
Neck	12.0	Waist	7.0

The measurements show defect in the breadth of the shoulders and depth of the chest. The ideal measurement according to one authority is:

Weight	113 pounds		Inches
	Inches	Girth: Neck	12.0
Height	64.5	Hips	34.5
Girth: Chest, ordinarily	31.0	Upper arm	10.0
Chest, empty	29.0	Forearm	8.75
Chest, full	34.0	Depth: Chest	8 0
Ninth rib, ordinarily	29.0	Abdomen	7.0
Ninth rib, empty	27.0	Breadth: Shoulders	14.1
Ninth rib, full	31.0	Hips	12.0
Waist	25.5	Waist	8.25

New York State has 11,171 physicians; Pennsylvania, 9,310; and Illinois, 8,112.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, June 9, 1894.

THE ASYLUM PHYSICIANS OFFICIALLY EXONERATED.

THE beginning of the proposed investigation of the New York City Asylums for the Insane, by the State Commission in Lunacy, has been postponed, but in the meantime the Grand Jury has been less dilatory. This body did the asylums the very best possible service last week, by calling before it the witnesses who, it was alleged, knew of abuses that would bring the asylum officials within the cognizance of the criminal law. After hearing this testimony the Grand Jury made a report that must be gratifying to the asylum physicians and to all true friends of the insane. This report, having briefly outlined the charges made against the asylum officials, says:

"After a consideration of the evidence adduced we are of the opinion that many of these charges are unfounded. In the main the asylums appear to be properly and well conducted. The system of treatment in vogue is appropriate and competently maintained. The physicians are earnest and considerate in the performance of their duties, and the treatment of the patients is marked with kindness. There has been no evidence before us showing any maladministration on the part of the asylum officials."

Having thus fully and explicitly exonerated the asylum physicians the Grand Jury report goes on to a consideration of the "manifest" evils that do exist in the asylums through overcrowding, lack of sufficient attendants, and the like, and then proceeds to fix the responsibility for these evils as follows:

"The commissioners have heretofore applied to the proper authorities for additional funds in order that the force of employees might be increased by an addition of the requisite number of attendants, but they failed to obtain the necessary sum, and the present insufficiency of the force is due to that fact. We earnestly recommend that the Board of Estimate and Apportionment appropriate the funds necessary for that purpose." It is also urged that the pay of attendants and of physicians be increased, and that "immediate action" be taken to provide more adequate quarters for the insane; all of which matters, of course, are controlled solely by the Board of Estimate and Apportionment.

Thus the result of the investigation by the Grand Jury is to fully sustain the views heretofore expressed in the RECORD, both as to existing conditions and the responsibility for them. The chief asylum physicians are fully exonerated; the Board of Apportionment is officially arraigned. It is high time for that Board to explain its shameless parsimony, if it can. But to those most familiar with the facts, it is no cause for surprise that the members of the Board have thus far remained silent. It is to be hoped that the investigation by the State Commission in Lunacy will, in the interest of reform, still further exploit the shortcomings of a Board whose niggardly provision for New York's dependants has so long disgraced our city.

THE SERUM-THERAPY OF TETANUS.

A REVIEW of recent progress in the serum-therapy of tetanus is contributed by Dr. J. P. Warbasse to the *Annals of Surgery* for June. The experiments and apparent successes of Tizzoni and Centanni have already been referred to in the RECORD. Berger's case, reported to the Academy of Medicine a year and a half ago, is also familiar. Berger's patient was treated with tetanus antitoxine prepared by Roux, about sixteen grammes of serum being used. The patient recovered, but the case is not a demonstrative one, because other remedies were employed. It is doubtful also if so small an amount of serum could be efficacious.

The most careful work in this line seems to be that which has been done by Behring. The experimenter found that he could not only render animals immune, but that it was possible to cure animals after tetanus had developed. After a year's work Behring found that he could obtain from a horse serum which had an immunizing strength of 1 to 1,000,000. That is to say, a gramme of the serum would render 1,000,000 grammes of animal immune. If the disease was developed, however, it took about 1,000 times as much to effect a cure. Rotter has reported a case in which an opportunity was given to make a test of the Behring serum.

A muscular young man received a wound of the hand, which was followed in eight days by tetanus. Thirteen days later the disease had progressed so that trismus and opisthotonos were present. Next day the patient was injected in the back with sixty-six grammes of blood-serum from an immunized horse, to this being added five per cent. of carbolic acid. The only narcotic given during the disease was ⅙ gr. of morphine. On the day following the injection, convulsions occurred as before. A second injection of fifty grammes was made in the pectoralis major with fresh serum, having an immunizing strength of 1 to 1,000,000. Next day the patient declared that he felt better. The muscular contractions persisted, but there were no further convulsions. Forty-five grammes of the same serum were injected on the following day, and the muscles of the face and back were much less rigid. On the fifth day of daily injections a final dose of fifty cubic centimetres of serum was injected. The improvement continued till the patient was up and about; on the ninth day after, treatment was discontinued. On the seventeenth day he left the clinic, and by the twenty-second all rigidity of the affected hand and forearm had disappeared.

Although a very large amount of the blood-serum had been used (250 grammes), no sign of harmful effect had been observed.

Since Richter has shown that in cases of tetanus which develop within six to ten days after the injury, the mortality is 4.4 per cent., the probability that Rotter's case was helped by the serum is very great. Still the experimenters continue to differ, and Büchner denies the validity of Behring's results.

THE FAVORITE DRUGS.

Mr. W. Martindale, F.C.S. of London, has prepared a most instructive little work, entitled "Analyses of Twelve Thousand Prescriptions" (H. K. Lewis, London). These prescriptions consist of 10,000 collected from pharmacies in Aberdeen, Bournemouth, Carlisle, Oxford, Cork, and 2,000 from London. They were all written within the last decade, and reflect quite fairly what drugs the average practitioner is using in Great Britain and Ireland. They include both officinal and non-officinal preparations.

The total number of drugs used we find to be 293, of which 84 are non-officinal. As a number of these are practically the same, but given in different combinations, one may conclude that a civilized nation at the present day requires somewhat over 200 drugs to soothe its pains, solicit its appetites, control its peristalses, and in general to promote eubiosis or insure euthanasia. This is, after all, not such an appalling number, especially when it is found that only 99 were used over one hundred times, the numbers sinking gradually to end ignominiously with 10 for "tinctures laxativæ." The list is headed with "spiritus chloroformi," of which there were 1,117 prescriptions. This addiction to spirits of chloroform is undoubtedly a prescription habit on the part of the English doctors, since the compound has no such popularity elsewhere, and since spirits of chloroform is only a comforting menstruum of little remedial value. The prescriptions for pure chloroform were only 54.

Next on the list comes tincture of nux vomica, of which there were 991 prescriptions. If to this we add those for strychnia in its other forms, the total becomes 1,536. It is clear that the sheet-anchor of the English practitioner is strychnine. One must conclude that his patients are a debilitated lot, and also that he himself is poor in expedients, since this one stimulant stands out so prominently. Quinine, to be sure, is given a good deal (598 prescriptions), but iron, administered in the form of the tooth-destroying tincture, is low in the list (249).

Bicarbonate of soda is a mighty factor in controlling the diseases of Great Britain, for it ranks next to nux vomica, 807, in the list of popular drugs: wine of ipecac, 504; bicarbonate of potash, 463; chloroform water, 437; bromide of potash, 365; nitro-hydrochloric acid, 357; iodide of potash, 356; arsenic, 337; salicylate of soda, 323; paregoric, 316; belladonna, 301; digitalis, 300; mercury, sulphuric acid, and bismuth, complete a list of the drugs which may fairly be considered as most frequently used.

They tell a story of asthenia, dyspepsia, rheumatism, syphilis, and bronchitis.

Opium in some of its forms is prescribed 849 times—a rather formidable percentage.

Sir James and Lady Paget celebrated their golden wedding on May 23d.

PEN-PICTURES IN ST. LOUIS.

St. Louis does not seem to be in perfect harmony as regards its candidates for the presidency of the American Medical Association. The *Weekly Medical Review* promised to give its readers a "pen-picture" of a supposed candidate, Dr. I. N. Love. But this latter gentleman, learning of the purpose, sent a letter to the editor, who very wisely printed it in place of the pen-picture. Dr. Love declares that he is not a candidate, and adds some paragraphs which form a contribution of solid value to the subject of pen pictures and brotherly love. He says:

"The tone of the editorials appearing in your publication, followed by the specific announcement that a faithful pen-picture will be presented in the next issue, is noted. I desire to give you, in the most emphatic manner, fair warning that in presenting any pen-picture of my personality you must have a care. When it comes to a matter of pen-pictures or personal journalism, I can assure you that I can hold my own with any Richmond that has yet appeared in the field or is likely to; and if I desire to enter into any such work, considering the vulnerability of the owner of the *Weekly Medical Review*, and the extreme vulnerability of the chief of the editorial staff, I do not think that there will be any question but that I can present some very readable matter, and if I am forced to the issue, I will do it in a manner to suit the queen's taste. There will not be a grease spot left of those whose pen-pictures are presented; but such matters are not agreeable to me. I am not in favor of personal journalism; and I give you this notice, that it is not my intention to engage in it; but, that I will hold you personally severally responsible for the utterances of your journal."

We rejoice that no breach in editorial amenities has occurred, and that the threatened extinction of the *Review* editors, even to the inclusion of the *locus adipis*, has been made as unlikely as it would have been deplorable.

AN APOLOGY FOR CHARLATANRY.

Massachusetts is a fine historic State, and one that keeps well in advance in most political and economic matters. But the solidity of its progress is now and then picturesquely, if not seriously, weakened by the activity of its more than average percentage of cranks. The anti-vaccinationists have been having very high jinks at the State House this past winter, and the quacks and mind-curers have until lately more than held their own in the legislative halls. Nothing, however, more curious, and we might add more characteristic, has appeared of late than the extenuation of a learned professor in Harvard College as a champion of mind-curers and the unlicensed and illiterate in medicine.

Professor William James, M.D., is known, admired, and esteemed as a professor of psychology, but he has developed for himself a new *rôle* by contributing a long letter to the *Boston Transcript* attacking the medical registration bill. The ground taken by him is equally unique and narrow, considering the fact that the man who takes it is an educated and, presumably, intelligent man. It is, that the regular medical profession does not devote itself enough to therapeutics, and that by allowing a free field for everyone, unhampered by tradition or technical

knowledge, new discoveries are more likely to be made and richer remedial results to flow. We are told that physicians, as a class, are too much interested in the scientific side of their profession, and too much trammelled by custom, to do all that is possible in the way of therapeutic advance. Therefore we should give the old women a chance.

One can hardly read this pleasing apology for the charlatan with patience; for the writer shows himself ignorant of medical history, out of touch with every-day medical work, and in sympathetic *rapport* only with psychic healers and the telepathic humbug which seems to thrive so freely upon the baked beans of Boston. We know no way of judging the future but by the past, and the past surely tells us that it is through the medical profession that therapeutics has been advanced to its present state. Every practising physician is daily a student of this branch, learning and contributing to it. Every patient is a new stimulus to effort, which is effective in accordance with his previous training and natural aptitudes; while with the quack it is in accordance simply with his natural aptitudes and the prospect of money.

But the broad question, after all, is simply this: Is not a community safer when it is supplied with educated or qualified practitioners of medicine, than if there is along with these a considerable percentage of ignorant and fraudulent medical men? These latter may sometimes cure, it is true, when the others fail. But we must be guided by general results, not by special cases.

The Massachusetts bill has passed the Legislature, and we trust by the time this appears that it will have become a law.

News of the Week.

Cook County Hospital.—The event of the year among the large body of senior medical students has just occurred, namely, the County Hospital examinations for internes. The outcome of the strike is that three were selected from the graduating class of Rush Medical College, two from the Northwestern University Medical School, and one from the College of Physicians and Surgeons. These internes serve eighteen months in the County Hospital, the period being divided into three divisions, allowing of six months' service on the medical side, six months' on the surgical, and a corresponding time in practical obstetrics. These positions are eagerly sought by the new graduates. The experience obtained is certainly a rich one.—*British Medical Journal.*

A Medical Centenarian.—Dr. Salmon, of South Wales, is the oldest doctor and Freemason in the kingdom. He attained in April the ripe age of one hundred and four. He joined the "mystic Masons" over eighty years ago, and he is the *doyen* of that body as well as of the Royal College of Surgeons. He has been a justice of the peace for forty six years, and he is also a deputy-lieutenant for Glamorgan. Within two miles of Dr. Salmon's residence there is a lady who was born the day after Dr. Salmon, and who is consequently also in the one hundred and fifth year of her age.

Recent Appointments at Jefferson Medical College.—At a recent meeting of the Board of Trustees of Jefferson Medical College, Dr. W. Joseph Hearn was elected Clinical Professor of Surgery; Dr. Edward P. Davis, Clinical Professor of Obstetrics; and Dr. S. MacCuen Smith, Clinical Professor of Otology.

Dr. Julius Althaus has resigned his post as senior physician to the Hospital for Epilepsy and Paralysis, Regent's Park, which he has held for the past twenty-eight years, and has been appointed consulting physician to that institution. Dr. Cagney has been appointed physician, with charge of in-patients.

"Phthisin" Crystals.—It was lately announced that Professor Schrön has been for some time engaged in attempting to isolate from the cultures of pathological micro-organisms and from the organs of patients dying from infectious diseases the poisons which are characteristic of each affection. According to some of his published researches it would appear that each micro organism secretes a particular poison, and that in the cultures of specific micro organisms and in the organs of patients and animals dying from specific diseases, certain crystals appear which differ according to the microbe which is the subject of investigation. Thus in phthisis particular crystals are found to which Schrön has given the name of "phthisin" crystals. It is difficult to form an opinion as to the value of Professor Schrön's researches, and we look forward with interest to their full publication. It would appear, however, that the so-called "phthisin" crystals have been seen by other observers, but have been designated by them under other names, having been previously described as altered blood pigments, or even as charcoal particles which had been absorbed from the lungs. It is hoped that Professor Schrön will not long delay the publication of his interesting memoir on this subject.—*British Medical Journal.*

Guilty of Assault for Vaccinating a Sick Man.—Dr. Henry L. Schelling, of Brooklyn, employed in the Department of Health as a vaccinator, on April 26th vaccinated one Emil Schaefer while the latter was ill in bed and despite his objections. In the Police Court last week Dr. Schelling was arraigned on the charge of assault. Mrs. Schaefer, in her testimony, said: "We argued with the doctor, but it was of no avail. I told him how sick my husband was, and that he wasn't expected to live, but the doctor said he would vaccinate him before he left the house." Dr. Schelling said he was acting under instructions of the Department of Health and was not violent. Justice Connolly found Dr. Schelling guilty, but suspended sentence.

The Woman's Medical College of the New York Infirmary held its twenty-sixth annual commencement on June 1st, and graduated a class of seventeen.

Death of Dr. Samuel T. Hubbard.—Dr. Hubbard, for many years one of the best known physicians in this city, died on June 1st in his eighty-seventh year.

Dr. Hubbard was born at Haddam, Conn., February 19, 1808, and received his early education at the Garfield Grammar School, Middletown, and at Suffield Academy, in Connecticut. He studied medicine with Dr. Amos S. Miller, of this city, and was graduated from the College of Physicians and Surgeons in the Class of '35. He was married in 1850 to Mary H., daughter of Benjamin Hustace, of this city.

Dr. Hubbard was a member of the County Medical Society, the New York Academy of Medicine, the Medi-

cal Journal Association, the Medico-Legal Society, the Society for the Relief of the Widows and Orphans of Medical Men, and the Physicians' Mutual Aid. He was President of the County Medical Society from 1866 to 1867, and held various offices in that and the other societies thereafter.

He was at one time physician to the Presbyterian Hospital, and consulting physician to the New York Dispensary, and was a Trustee of the College of Physicians and Surgeons.

The French Medical Press Association.—The French Medical Press Association held its second annual dinner on May 11th, in Paris, Dr. de Ranse in the chair. Seventeen members were present. A letter from the Czar, acknowledging the courtesy paid to the medical officers of the Russian squadron, was read by the Secretary.

A New Device.—Dr. Byron Robinson, of Chicago, announces a new device for intestinal anastomosis. It consists of two metal discs around whose circumference there is a groove. In the groove is placed a hollow rubber tube. The two discs are clamped together with a ratchet or spiral screw. The principle on which the device works is the same as Dennan's cylinders. The gut is gradually necrosed through by slow elastic pressure. The rubber tube and pressure can be so controlled that the circular line of union may be of determined width. The elastic pressure avoids lateral fistula from too rapid or too violent force. The device is called the "rubber-faced disc."

Freckles and the Red Parasol.—The fashionable "fad" in Chicago of the red parasol is now defended on the ground that it is an efficient freckle preventer—the actinic rays of the sun, which it is claimed are the cause of the pigmentation, being intercepted in passing through a red medium —*Journal of the Amer. Med. Association.*

A New Hospital for Male Tuberculous Children is to be opened at Ormesson, Villiers sur-Marne, France. It is intended to accommodate eighty patients. The heating apparatus and ventilating and other arrangements will occupy the basement. Above this are the wards, nearly forty feet high, around which run galleries in which are the beds, leaving a central space. The cubic space will be 120 cubic metres per bed. A very complicated system of ventilation is to be adopted, and medicated air is to be supplied to the wards both morning and evening. A similar hospital for female children exists at Villepinte.

The Classics Again.—The recent agitation in France concerning the reform in medical education and examinations turned principally on the question whether the study of classical language should be included in the curriculum. A commission, comprising the rector of the Faculty of Medicine and five professors, returned their answer to the following intent: The physician is obliged to use a terminology which is derived from the Greek and the Latin. Although he may—without having been instructed in the classics—in the course of time acquire a superficial knowledge of the expressions, still there will remain in such a case a sentiment of inferiority, because he does not know their origin. In the interest of the profession the sentiment should be spared the future physician. Though there is a certain indirectness in this reply, there can be but one reading of the decision. In addition to the above, the commission wisely suggested the expediency of the medical faculty being conversant with at least one modern language. Indeed, as a contemporary points out on this subject, considering the present condition of medical science, deriving as it does its elements from all parts of the world, every physician should be somewhat of a polyglot.

Child Crying in Utero during Version.—Dr. E. Grandin (*New York Journal of Gynecology and Obstetrics*, April, 1894) observed this phenomenon during turning. The child was large and the pelvic brim contracted. As the foot appeared at the vulva, the child's head occupying the upper uterine segment, a distinct cry was heard resembling that of an angry child. With each traction of the foot the cry was repeated, being heard by Grandin, Marion Sims, and two nurses. With emergence of the trunk the crying ceased. The child was born asphyxiated, but speedily revived. The air-passages contained no liquor amnii. M. McLean has recorded a similar case. The explanation was simple: Air obtained entrance into the uterus during the first step in podalic version. S. Marx, in a case of contracted pelvis, attempted to deliver rapidly by introducing the hand and seizing the leg. The child cried during this manœuvre, as though smothered under a pillow. It was born asphyxiated, and could not be resuscitated. H. L. Collyer heard a child cry several times when traction was being made on its head with forceps. At once turning was performed, but the child was born dead.

The Offspring of Young Mothers.—At the Congress of Hygiene, Dr. Korosi, of Buda Pesth, stated that the proportion of deaths among children from weakly constitutions, or maladies traceable to the mother, was twice as large among the children of mothers under twenty as among the children of mothers over thirty. The author of this statement seemed pretty sure of his facts, since they were consequent upon a comparison of several thousand cases. His investigations on the subject showed further that the healthiest offspring was born of mothers between twenty and thirty, united to husbands between thirty and forty. In Hungary fifteen per cent. of the number of marriages shows that the brides are under twenty years of age, and in England twenty per cent.

A Dietetic Experiment.—The medical department of one of the infantry regiments of the Guards stationed in Berlin is engaged in carrying on gastronomic experiments, not on the usual patient laboratory animals, but on medical students (candidates for the army surgeon examination) who volunteer to serve as subjects of experiment. These young martyrs to science undertake to eat and drink nothing beyond the regimental rations during the period of observation, which lasts from a fortnight to four weeks. Daily they may be seen in full equipment marching out with the regiment sharing its fatigues to the full. Immediately on their return to barracks every day they turn into the Charité Hospital, where their temperature is taken—pulse, body weight, amount of perspiration, etc., registered, and even the stomach pump used on some of the most devoted. These experiments, which are carried out with true German thoroughness, are to furnish data for further improvement in the nutritive value of food supplied to soldiers on the march.—*British Medical Journal.*

Fatal Ivy-Poisoning.—Five school boys died during the past week at Tarrytown, N. Y., the result of eating the root of the Rhus Toxicodendron. The symptoms of the poisoning were: stupor, dilatation of pupils, nausea, thirst, feeble irregular pulse, tremors, convulsions, and finally collapse. We are not aware of any similar cases resulting in death.

A Circumcision "Specialist."—The trials of paternity, says the *British Medical Journal*, are evidently increased in no small degree by announcing the important event in the papers. Some men receive the congratulations of their friends in a meek and subdued spirit, appreciating full well the gravity of the occasion and the responsibilities thereof. Others seem to revel in the proud position, rushing quickly to the newspapers to announce the glad news—and they have their reward; specimens of soaps, night-lights, and puff-powders, with circulars advertising basinettes, dressing-gowns, perambulators, and every possible description of condensed milk and rickets-producing food are poured upon him by the dozen. Among the advertisers of the less pleasant sort who play upon the anxieties of the new-made parent is the "specialist operator" for circumcision! We have received the circular of one of these gentlemen which straightway followed an announcement of the birth of a son, in which the advertiser—although greatly hampered by bad grammar—endeavors to show the importance of the youngster being circumcised without delay, and offers to do the operation within half a minute in an ordinary case and within a minute even in the most difficult. Among the moral and physical reasons for its performance he somewhat obscurely says that "Every Circumcised person have always been so hardy and thereby escaping obscure nervous disorders, the facts of which are acknowledged by highest medical authorities.". Possibly he hopes that the father also may like to be performed upon, as he goes on to say: "Every invalid or victim of some obscure nervous disorder should not neglect this, as it will materially assist in restoring him to health." Perhaps, however, the attraction may not prove irresistible after all, for with better grip of grammar but less idea of sense, he continues: "What are the benefits derived therefrom? Predisposition to and Exemption and Immunity from disease"—which seem somewhat mixed advantages.

An Interesting Theory of Depopulation.—In an elaborate essay on the "Origin of Neoplasms in General, and of Cancer in Particular," now in course of publication in the *Progrès Médical*, M. A. Wassilieff formulates the following "general law:" "Living matter reproduces itself more readily the more inferior it is, other things being equal." In this formula, we are assured, is contained the general theory of the development of all new growths. But the "law," according to our author, has a much wider application than this. It explains, among other things, the depopulation of France, which is causing some alarm to French statesmen. M. Wassilieff's view is that "what is erroneously called 'the depopulation of France,'" is, in fact, a conclusive proof of the innate superiority of that nation to all others. While inferior countries like England and Germany are increasing and multiplying like the lowly organized bodies they are, the French race is dying of its own greatness. Whether the French people will find consolation for their approaching absorption into the infinite in the consciousness of their superiority may be open to doubt.

"Mushroom" Colleges.—Moved thereto by the apprehension that the degree of M.D. "is in danger of being greatly reduced by the organization of mushroom colleges in various parts of the State as well as in other States," the State Board of Medical Examiners of Iowa adopted the following resolution at its recent meeting:

"*Resolved*, That no medical college shall be recognized by this Board as in good standing until it has maintained a reputable existence for five years, provided this regulation shall not apply to colleges already so recognized."

A similar resolution of the Illinois Board, adopted in July, 1892, was rescinded at its January, 1894, meeting. —*Journal of the American Medical Association.*

Why There are Eleven Medical Colleges in St. Louis.—The Chancellor of Washington University, of St. Louis, Professor W. S. Chaplin, made these remarks regarding medical education in Missouri at a recent meeting of the Standard Medical Alumni Association. He said: "Don't think for a minute that these many medical schools in the West have been established for purely pecuniary reasons. The doctors do not make enough out of them certainly to pay for the work which they put into them. They might make more money, probably, by sawing wood the same amount of time. They do it in order to establish themselves as specialists. They have no other reason. Is this not a case where you have put on too much restriction in one direction? And that has produced an abnormal growth in another direction. If you look into the history of these medical schools you find that there was a time when there was but one medical school. Some fifty years back, in St. Louis, I believe, there was just one. Then, by a process which the naturalists understand perfectly, by the growth of a kind of septum across the medical school, suddenly there were two medical schools, equipped fully, and those two medical schools were running in the most violent opposition. Here, in the East, I understand the medical profession have none of these differences and troubles; but in the West every medical school means a new set of mutual admirers. The professor of ophthalmology sends all his cases of surgery to the surgeon who is connected with his medical school. Go into St. Louis to-day, and you find just eleven sets of men who generally recommend and send all their patients to the men connected with their own schools. I do not despair of medical education in the West. I hope there will be constant and rapid deaths among the medical schools. The condition is certainly a disgusting one, when viewed from the point of education."

Dr. Albert Day, for nearly forty years identified with the Washingtonian Home for Inebriates, Boston, as its superintendent, died recently.

Another Missouri College.—The Central Medical College of St. Joseph, Mo., has been organized to replace the Northwestern Medical College of that city, suspended because of the refusal of the Missouri State Board of Health to recognize its diplomas.

Society Reports.

American Medical Association.

Forty fifth Annual Meeting, held in San Francisco, Cal., June 5, 6, 7, and 8, 1894.

(By Telegraph to the MEDICAL RECORD.)

THE forty-fifth annual meeting of the American Medical Association was held at I. O. O. F. Hall, San Francisco, and was called to order at 10 A.M., Tuesday, June 5th, by President James F. Hibberd, of Indiana. On the platform were seated Dr. I. N. Love, of Missouri, Second Vice-President; Dr. William B. Atkinson, of Pennsylvania, Permanent Secretary; Dr. H B. Ellis, of Los Angeles, Assistant Secretary; Dr. J. Simmons, President of California State Society; Dr. R. H. Plummer, Chairman of Committee of Arrangements. Prayer by Rev. Dr. Robert McKenzie. Governor Markham and Mayor Ellert were unavoidably detained.

Addresses of Welcome.—Supervisor J. G. James, on behalf of the Mayor of San Francisco, extended a hearty welcome to the members and tendered the freedom of the city. Dr. J. L. Dimmons, of Sacramento, followed in behalf of the California Medical Society, and delivered the Address of Welcome.

DR. R. H. PLUMMER, Chairman of the Committee of Arrangements, offered instructions and information to delegates and visitors. After which he presented a gavel to President Hibberd. The handle was of orange-wood, which is the State color—yellow; body of manzanita wood, peculiar to the Pacific slope; sides, gold, inscribed "A. M. A., 1894;" on the obverse was "James F. Hibberd, President."

The physicians of Oregon, by the courtesy of Dr. W. G. Owens, sent one dozen gavels for use in the various sections; the handles were of yew-wood, and the body of myrtle.

President JAMES F. HIBBERD prefaced his address with the following remarks: "Some of the pleasantest surprises of my life are occurring at the close of my career; the sentiment which prompted the gift is more appreciated than the gift itself. I will endeavor to use it discreetly and properly. I can stand any number of such surprises."

He then continued as follows: At every annual meeting the Permanent Secretary and the Treasurer have difficulty in appeasing delegates who are not received, because the credentials presented by them have not been issued by a society entitled to representation in the Association. The difficulty lies in the fact that some of the State societies are not representative bodies, and consequently the constitutional provision cuts off all delegates from such States except those commissioned by the State Society itself. While this is the letter of the law, it is not the spirit that animates the organization of the Association. The constitution should be revised in this particular, at least; every County Society in each State should be represented in its State Society. In this connection I desire to lay before you some thoughts touching the arrangement of subordinate medical societies in their relation to the American Medical Association.

Every medical man who belongs to any medical society should belong to a county, or an equivalent, medical society, and every member of a County Society should be *ipse facto* a member of his State Society, and this should be an open sesame to the American Medical Association. By this arrangement all reputable physicians in the United States would be brought together in the common fold, whose power for good within its legitimate sphere would be limited only by its aggregate wit and energy. Such a consummation would elevate the American profession to a plane for useful work the highest conceivable for the disciples of scientific medicine. A sentiment seems to be current among some of the members that indicates a misconception of the character and personnel of the sections, as I view them, regarding the propriety of conferring on the Business Committee the functions of the Nominating Committee. They say, "The Business Committee is made up of the ex-chairmen of sections; the sections are in the hands of the specialists; the specialists reside in the greater cities, and consequently the Business Committee will be constituted of special practitioners who hail from the cities, some of which are large enough to furnish half-a dozen chairmen at once. This will not only exclude general practitioners from a voice in the selections of officers of the Association, but may, by chance or design, place the general business of the Association under the management of specialists from a few important cities of the country."

The error of this representation is the fact that its entertainers fail to recognize that the aggregate membership of the sections at each annual session is the total membership of the Association in attendance. True, in each section there will be members of the special society whose work is the same as that to which the section is devoted, and there will be others whose engagements are limited to the same line of practice; but these combined, except in two or three sections, will not number more than a small minority, probably not a tenth of those enrolled in the section. The other nine-tenths will be general practitioners, whose professional proclivities have directed them to the section; and these general practitioners have the power by their votes to elect the best man in the section to its chairmanship, without inquiry whether he lives in a big city or in a hamlet; and in so doing will make it patent to every thoughtful mind that the personnel of the Business Committee will be selected under conditions to insure as intelligent, as well distributed, and trustworthy a committee as the Association can secure. Moreover, the function of a Nominating Committee is to nominate, not elect; confirmation or substitution is in the authority of, and always exercised by, the Association. I am led to present this subject in this light and to this extent, because I feel that a majority of the members recognize the imperfections of our present mode of selecting the Nominating Committee, and realize that the welfare of the Association calls for a committee to exercise the important functions of the Nominating Committee, which has elements of permanency in its organization, and whose personnel has been selected with something of deliberation. The Chairman of the Committee on Military Affairs at Washington has concluded there is a surplus of assistant surgeons, and in his report to the House reduced the number from one hundred and twenty-five to ninety. This recommendation has passed the House, and if it should be approved by the Senate will greatly embarrass the medical service of the army, and in the end be a detriment to the country. Let the American Medical Association at once call the attention of Congress to the mistake threatened. An effort should be made by this Association to restore a part of the appropriation for the support of the National Medical Library, which was dropped by the last Congress. For twelve years the appropriation was $10,000, but the last Congress reduced it to $7,000, and the present Congress proposes to continue the reduction still more. The desirability of supervision of public health by the general Government has been recognized by this Association for many years, and manifested in various ways. Various sanitary organizations have entered Congress with petitions, asking that the general Government be clothed with authority to execute measures to assist in protecting public health. The outlook at this time for securing a Bureau of Public Health during this session of Congress, is not encouraging. At present there is no measure formulated in this behalf.

So worthy of support is the New York Academy bill now in Congress, it seems to me the reasonable duty of this Association at this time to declare and proclaim its unabated faith in the virtue of vaccine to protect from small-pox, to render persons as immune against variola as an attack of variola itself, and that it is innocent of all

mischief when the vaccination is done by a vaccinator who is competent judge of both the purity of the virus and the fitness of the vaccine.

Much has been done in advancing the extent and character of the collegiate instruction of medical students. Certainly the Association has ground to congratulate itself on the fruits of its persevering labors to secure more thorough medical education. The Congress of Medicine in the immediate future must be along biological lines; the microscope has revolutionized our knowledge of the world of living things, and to us have been discovered the generators of the most extensive, persistent, and malignant epidemics that periodically decimate the earth, as well as intractable and fatal disorders that are always with us. Another line of biological workers have carried us back through the morphology of organs, tissues, and cells, to the origin of vital activity in protoplasm, and still more important in being. So have given us glimpses of the origin and development of the somatic mind that will, when the scheme of nervous organization and function shall be clearly portrayed, dissolve the mystery that has in the past obscured our realization of the true nature of hypnotism, Christian science, and other anomalous neuroses which the sciolists, and in an especial manner those claiming to be doctors, are promulgating and practising, to the discredit of true scientists and the injury of the weak-minded and ignorant classes.

We should apotheosize protoplasm, the dividing line between organic and inorganic matter, itself at once the result of the law of perpetual motion with which the Creator endowed the atoms of elemental matter, and the beginning of that phase of energy known as vital activity which constitutes the entire vegetable and animal kingdom. No one people or class of people can claim exclusively to have opened the way into this more primitive arcana of nature. The physicists of all nations, botanists, zoölogists, anatomists, physiologists, and their congeners, have all participated in this progress. The distinction of Schawn, Virchow, Ferrier, Jackson, Pasteur, Koch, and Sternberg is due to their advanced study of biology.

It is apparent to all who have given attention to the matter of remodelling the constitution, that there is much feeling among the members who have been active in working up the changes that will be offered as a substitute for the constitution as it now exists. It is right that a fair and unbiassed expression of the will of the Association, according to the method prescribed by our laws, should be secured; and in so doing there is nothing to excite passion nor interfere with that calm deliberation that distinguishes the proceedings of an assembly composed of cultured and refined people seeking the welfare of the guild to which they belong. And so with the code of ethics; for years there has been a feeling among many most excellent and intelligent working members of the guild, that the code did not fairly accord with the demands of the advanced profession in their intercourse with each other, nor with the proper reciprocal relations between the profession and the public; while, on the other hand, many members, equally intelligent and devoted to the Association, have felt that the code of ethics that has guided the Association through nearly half a century prosperously and honorably, and which is still a reliable guide in every advanced thought and action, cannot be bettered for our present status, and should not be disturbed.

Touching the sufficiency of the constitution and code of ethics of the American Association as they are now, I have well settled convictions, the result of many years' observation, experience, and reflection; but I am not here to proselyte my opinions. As I interpret my mission on this occasion, it is to exercise my influence and use my authority to secure to those here entitled to vote a clear expression of untrammelled judgment, and to encourage a cheerful acquiescence of all parties in whatever conclusion may be reached.

On motion of Dr. W. T. Bishop, of Pennsylvania, the address was referred to a committee of five for consideration. The following committee was appointed by Dr. I. N. Love, acting president: Drs. W. T. Bishop, of Pennsylvania; Lyman Beecher Todd, of Kentucky; R. Deverly Col, of San Francisco; Fred W. Mann, of Michigan; and J. P. Woodbridge, of Michigan.

Dr. N. Quimby moved that a committee of five be appointed to especially consider the danger of a reduction of the number of surgeons of the army. The following committee was appointed: Drs. I. N. Quimby, of New Jersey; J. Copeland, of Alabama; J. B. Hamilton, of Indiana; E. E. Montgomery, of Pennsylvania; and J. M. Duef, of Pittsburg.

On motion, Dr. Edward C. Ingalls, of Chicago, was elected a member of the congress by invitation. On motion, the delegates from the Pharmaceutical Association were invited to seats.

The Treasurer's Report was read by the permanent secretary, owing to the illness of the treasurer. Dr. Ingalls presented the treasurer's report in detail, endorsed by Drs. E. E. Montgomery and E. Fletcher Ingalls. On motion of Dr. Hume, the report was received and filed.

The Report of the Secretary Regarding Revision of the Code.—The report stated that the States opposed to change were 21; in favor—Nebraska, Vermont, Indiana, 3; laid on table—Wisconsin, Florida, 2; not yet considered, 3; no reply, 11.

The Report of the Pan-American Medical Congress has not yet been received.

Election of Delegates to the Nominating Committee was then proceeded with. A resolution was offered by Dr. L. D. Dulkly, of San Bernardino, on behalf of the business committee:

Whereas, Each section should have three members on the business committee of the association, and

Whereas, A considerable number have signified their inability to be present this year;

Resolved, That the officers of the various sections be hereby instructed to appoint from the members in attendance, alternates to act at this meeting for those who are unable to be present.

Resolution No. 2:

Whereas, Dr. R. J. Dunglison has been for seventeen years a faithful, energetic treasurer of this Association without any compensation; therefore be it,

Resolved, That the hearty and unreserved thanks of this Association be cordially extended to him for his efficient and laborious duties on behalf of this Association, and a copy of this resolution be forwarded by the secretary to Dr. Dunglison.

Amended by Dr. Montgomery, to present to Dr. Dunglison $300 as appreciation of services.

The meeting then adjourned.

Second Day, Wednesday, June 6th.

The General Session was called to order by President Hibberd at noon.

Report of the Committee of Arrangements.—The following resolution was offered by Dr. Quimby, of New Jersey:

Resolved, That the American Medical Association urge upon Congress the advisability of preserving and promoting the efficiency of the Army Medical Department.

Resolved, That any reduction in the present membership of the Army Medical Department, or of its appropriation, would be prejudicial to the interests of the army and of the country. And be it,

Further Resolved, That the Secretary be instructed to thus inform Congress by telegraph.

The resolution was carried.

The Nervous System in Disease, and the Practice of Medicine from a Neurological Standpoint, was the subject of an address by Dr. C. H. Hughes, of St. Louis.

In this age of pre-eminent progress in every department

of human research, I congratulate you on the onward march medicine has made, and is yet making, toward the mitigation of human misery and the mastery of disease; and especially on the part American medicine has taken in the scientific triumphs of the closing century over the encompassing elements and environments adverse to man's health and strength, and consequent happiness and efficiency in the affairs of life. As our father Hippocrates drove the devotees of superstition from the Temple of Hygeia, and taught the people that offended gods could neither bring nor propitiate God's direful diseases; and as Andreas Vesalius dared the popular prejudice and the ecclesiastical power of his day to make his first human dissection; so we, his professional descendants, continue breaking down the barrier of ignorance, of prejudice, and superstition in the way of man's happiness and prosperity; unlocking the secrets of nature's arcanum, and setting the captive mind and organism free from the enthralment of disease. Substitutive inoculations, for establishing tolerance and immunity from other diseases, are spreading the rescuing power of the profession. Consumption, with its one hundred and sixty-five thousand annual victims in this country alone, will soon be a thing of the past, through wisely applied antisepsis. Electroscopic and other explorations now penetrate the dark and otherwise hidden places of the human body, making it a glow of light to the diagnostician. But little, if any, of the human anatomy is absolutely beyond the reach of our science or relief. The abdominal cavity is no longer a *terra incognita* to the resources of surgery, thanks to Joseph Lister, of London; McDowell, of Kentucky; Battey, of Georgia; Lane, Gross, Agnew, Frank Hamilton, and John Hodgen.

The once hidden recesses of the brain also are now with impunity penetrated to where our ancestors dared not go, saving lives and minds formerly doomed to destruction. Thanks to Fritsch and Hitzig, of Germany, Ferrier, Horsley, and Macewen, of Great Britain, and Bartholow, of America, the latter having been the first physician in the world to explore and prove the truth of cerebral localization by demonstrations on the living human brain. Science now penetrates to the very dwelling-place of thought and volitional motor impulses in the cerebral cortex, saving by modern neurology and cerebral surgery. The grip and pneumonia is such as might come from sections of the vagi. The vagus largely governs the lungs, the heart, and the circulation of this disease, and toxic irritation and depression of the medulla and pons explain most of its symptoms.

The therapeutic lesson of the neuropathic implications of influenza is rest and reconstruction (pending the search after its causative bacteria and their proper bactericide); rest and reconstruction, that phagocytosis may be promoted in the blood. Chloral as the best antiseptic, hypnotic, and calmative, for even the delirious stage. In the latter, ammonium bromide added for the pain; the coal-tar derivative analgesics, and sweat-producing opiate combinations, the elimination of all disturbers and depressers of nerve-centres entering through the blood, like the rheumatic and malarial or venereal poison. It is through the neural connections of the brain and stomach that the acknowledged apepsia of neurology is a clinical fact. The brain influences the stomach, and the stomach influences the brain, but the power of the former over the latter is far greater than the latter over the former. To concede this influence of the nervous system over the digestive processes, we need not ignore any fact of chemico-biological research; the liver, the kidneys, the bladder, and the bowels are similarly influenced by emotion, and the lymphatic system is likewise under nervous control, like the arterioles by the vaso-motors.

A centre in the medulla also influences through the chorda tympani nerve, and probably the sympathetic, the salivary secretion. A centre there also influences the action of the kidneys.

Salivary secretion is induced reflexly by mastication and the irritation of the presence of food in the mouth and stomach, and by the vivid remembrance of certain foods whose eating has made an agreeable impression, and by emotion. We swallow, we digest, we sob, we vomit by means of vagus fibres; and its fibres go to the cœlic plexus, the spleen, the liver, the kidneys, and the small intestine. Œsophagismus, gastrodynia, or cardialgia, tachycardia, palpitation, and angina pectoris, and spleen, intestines, liver, and kidneys, are influenced by this wonderful nerve, as well as asthma and exophthalmic goitre and many affections of the larynx and lower air-passages. Notwithstanding, the complete pathology of this wonderful nerve, and of many of the interesting diseases connected with it, may be said to be yet somewhat obscure. The vagus and the vaso-motors influence or govern circulation, respiration, and digestion.

The dominion of the nervous system over the spleen is one of the concessions of the physiology of our day. Stimulation of the medulla leads to contraction of this organ; not only its arteries, but the organ as a whole, is maintained in a state of tonic contraction, to a certain extent, through the agency of the nervous system.

Hysteria illustrates, in an especially forcible manner from the standpoint of clinical observation, how suddenly and how extensively nearly all the organs of the body may be profoundly disordered in function by morbid impression through the nervous system. There is a suggestive practical lesson in this "neuromimesis," or mimic neurosis, as to the relation of the nervous system to diseases in general. As the study of this disease led Goodell to discern and portray the nerve counterfeits of uterine diseases, and to say "the crying error of the day is the mistaking of nerve diseases for womb diseases," so I say of disease in general, the crying error of the day is the ignoring of neuropathic implications, concomitants and sequences of organic, visceral, and general diseases, and the mistaking of nervous and other diseases.

The *vis medicatrix naturæ* resides in the nerve-centres, and in their power to maintain, under stress of invading disease, the normal metabolism in the various organs, and as I believe, though this is not yet susceptible of scientific proof, of the furnishing and multiplying of the phagocytic hosts of conservative destruction in the healthy blood.

The Importance of Early Recognizing Neurasthenia.—Neurasthenia, or general functional neuratrophia, shows itself chiefly in the brain, and is psychically characterized by timidity of conduct, nervous irritability, and morbid fears, bordering on, but not becoming delusions; and physically by functional atonicity of the viscera, especially of the stomach, heart, bowels, and motor and psychical areas of the brain. It is the cause and source of apepsia nervosa and of cerebro-spinal irritation, and differs from hysteria, with which it is sometimes mistakenly confounded, in being continuous and not paroxysmal, and in being far more common in men than in women.

The question of the parasitic origin of this disease was left *sub judice* at the last International Congress at Rome, at the close of the most interesting and learned discussion ever held upon the subject. The same light has lately dawned on gynecology and every department of medical practice. We are approaching an era when the whole patient is to be treated; no more only a part or organ solely; and neurology will have a paramount place in general clinical medicine, notwithstanding the recognized and merited advances of bacteriology in pathogenesis.

Certain heart affections proceed from the brain. What is true of the influence of the nervous system over the stomach in dyspepsia, and the lungs in the pneumonia of influenza, is also true of its influence in the production of certain diseases of the heart. They come from states of the brain. When the heart is severed from the central nervous system by section of the vagus nerves, a destruction of the vagus centre takes place by traumatism or disease. Profound changes in the heart's structure ensue; this points to central trophic influence

through the vagi, and to the often central nervous origin of heart disease.

The regularity of the heart's rhythm from and strengthening of its beat through vagus stimulation and central stimulation, as well as by certain volatile and internal stimulants, is suggestive. As we recognize psychic influence over our physiological life, over physical and mental habits, so must we come to acknowledge it the more generally in our dealings with disease. The physiological law that habit in the psychical life develops a tendency to recurrence is also exemplified in the disposition of certain diseases to recur; and the inter-relation between muscular and mental tonus suggests the importance of maintaining the psychical tonus in the treatment of all diseases, and the successful therapeutics of hypnotism proves it in many.

Hæmophilia and the Vasomotor System.—The neuropathic source of hæmophilia in the vasomotor system is more probable than any asserted dyscrasia of the blood. It is through the nervous system that we may understand how the hair turns in melancholia and may thicken in chronic mania or dementia of the less distressed and more stupid and inactive forms; how its color may turn from dark to white and back again to dark with the access and recovery of recurrent insanity; how it may gloss and dry, erect or flatten, be lost and regained under mental states; how the teeth may decay, the bones and nails grow brittle, and the skin harsh from the same cause; and how, from neuritis, the nails transform and the limbs waste as well as fail in sensibility and mobility, besides the œdematous, pigmentary, and horny changes of the skin from nerve-injuries.

Bad Temperature and Fever Dependent on the Conditions of the Nervous System.—That remarkable phenomenon, the uniformity of the temperature of the human body at all altitudes and all seasons, is due to regulating adjustment through the nervous system, and when temperature is disturbed it is due to irritation, mechanical, chemical, or toxic, of the nervous system, as in traumatic violence, microbic, septic, or drug disturbances the nervous system is the supreme ruler in the organism. When disease enters, it is weakened; when death takes place, it is dethroned. The germs of malaria, tubercle, cholera, typhoid, tetanus, etc., or the living virus of any fever make no fatal inroads until they break down and destroy centres of neural control and resistance. Whatever view we may take of bacilli, bacteria, or cocci, which eye or glass may reveal to us in the damaged organism; whether we regard them as carrion about a carcass, rats forsaking a sinking ship, thieving, destroying, or scavenger parasites, one thing is certain, disease becomes manifest only after the mechanisms of neural sensation, emotion, ideation, or control reveal it; for, as I have elsewhere said, the nervous system is the central executive and universal sentinel system of the organism. It governs and legislates for the physiological body, exercising moving, restraining, regulating, or inhibitory power over organic processes in health and in disease. It has its subordinate tributary and sustaining forces in the glandular, vascular, osseous, and other systems. A change in the weather or a certain exposure sends one man to bed with rheumatism, another with pneumonia, and a third comes down with intermittent or remittent fever or phthisis. We say uric acid in the first case, pneumococci in the second, malaria in the third, and tubercle bacilli in the fourth.

And now in the sunlight of advancing science, and of the approaching twentieth century, I proclaim that neuriatry and the practice of general medicine are practically one. The practice of medicine is rapidly becoming one of neurological methods, of neuriatry and psychiatry; and the best neurologist, all other attainments being equal, must of necessity make the best general practitioner. The boon of hypnosis and narcosis under the many methods for its induction known to our art, saving the insomniac from the precipice of mental overthrow or neural failure in the lower centres of the cerebro-spinal axis or peripheral nervous system; the power of antisepsis, and through it the wonderful procedures and possibilities of modern surgery, and this *fin de siècle* hygiene; the many and marvellous therapeutic and hygienic advances in promoting the phagocytosis of the toxic bacteria, the destruction of the ptomaïnes, and in other directions of relief and cure: the discoveries of pathology, histology, medical chemistry, biology, neurology, psychology, psychiatry, and the contributions of surgery, gynecology, ophthalmology, otology, laryngology, proctology, and the other specialties of study and work, have made the later decades of the present century the most memorable in resourceful discovery in the history of medicine or in the history of mankind. Intravenous injections of immune animal blood-serum promise much for the cure of phthisis and other chronic contagious diseases, and there appears good therapeutic promise for the coming years in mycodermic medication.

Dr. Didama, of New York, moved that thanks be extended to Dr. Hughes for his paper read. Carried.

A resolution was offered by Dr. Marcy, of Boston, recommending the appointment of State examining boards. Carried.

The report of the Journal was adopted as the sentiment of the American Medical Association. The Association then adjourned to meet at 10.30 A.M., on Thursday, for special consideration of the constitution and code revision.

Dr. Dunglison tendered his resignation as treasurer yesterday.

The Course of Bullets.—Professor Victor Horsley read a very interesting paper before the Royal Institution recently on the effect of modern small projectiles. In the course of his remarks he said: "Some people seem to think that a small bullet at a very high speed will pierce the tissues of the body without doing much general damage. This, however, is erroneous. The bullet hurries forward with it particles of the substance through which it is passing and thus practically becomes a larger projectile. If a bullet be fired through a book, it cuts out disks of increasing diameter as it traverses the pages. Hence, too, it is plain that the greater the sectional area the greater the damage. As to the heating of the bullet, it has certainly been much exaggerated, and its effects, if indeed it has any, may be safely neglected. The physical constitution of a body has a most important bearing upon the behavior of a bullet entering it. Why does a bullet of certain size and travelling at a certain rate simply perforate some substances, such as wood or iron, while in others, such as clay, brain, etc., it exercises a bursting and disruptive action? The answer is quite simple: the destructive effects vary directly as the viscosity of the body. This was established by some remarkable researches on the effects of bullets on soft tissues made by Huguier after he had observed the results of the wounds inflicted in the fighting in Paris in 1848. He suggested, from observations made on certain dead organs, such as lung, that the reason of the great lateral disturbance was that the tissues contained water in large quantity, and that the energy of the moving projectile being imparted to the particles of water caused the dispersion of these in a hydrodynamic fashion. This suggestion was shown to be correct by Kocher in 1874–1876. If a shot be fired through two tin canisters of equal size, the one full of dry lint and the other of wet, it will simply perforate the former, but cause the latter to burst explosively. In the same way shots fired into dough have more or less disruptive effect according to the percentage of water in the dough, and in general the more fluid the substance the greater the destruction. Now, in life the brain is a more or less fluid body, though in a state of rigor mortis it is practically a solid, owing to coagulation of the blood and protoplasm. Hence, a shot fired into the skull must have a disruptive effect and tend to burst it."

Congress of American Physicians and Surgeons.

Third Triennial Meeting, held at Washington, D. C., May 29, 30, 31, and June 1, 1894.

(Continued from page 699.)

THIRD DAY, THURSDAY, MAY 31ST.

Surgical Aspect of Nephritis.—This session of the Congress was under the direction of the American Association of Genito-Urinary Surgeons, and the subject for discussion was "Nephritis in Its Surgical Aspects."

DR. EDWARD L. KEYES, of New York, opened the discussion. He announced his intention of confining himself to a consideration of that form of surgical nephritis in which suppuration occurred, either spontaneously in the course of suppurative disease of the urinary tract below (ascending pyelonephritis), or originating below as a result of infection by the surgeon, or in the blood (the descending variety)—all the various forms of so-called surgical kidney. His paper was divided into three parts—Introductory, Practical, and Bacteriological. In the first section he demonstrated by a plentiful quotation of authorities, mainly French and German: 1, without microbic infection suppuration of the kidney was impossible; 2, the bacilli found most often were notably the bacterium coli communis, less often the staphylococcus pyogenes aureus; 3, these bacilli found entrance in a variety of alleged ways; 4, the introduction alone of these bacilli did not occasion ascending pyelitis, or even necessarily cystitis; 5, the soil was made receptive for microbic invasion by a variety of local physical maladies, *i.e.*, anything which interfered with the free urinary outflow by over-distention, also by traumatism, or failure of general vitality of the individual, and the kidney was especially prepared for invasion by dilatation of the ureters.

The second part of the paper contained the author's personal views upon urinary asepsis and antisepsis, and detailed his methods of every-day clinical work, the solutions he used, and his method of instituting catheter life upon the old subject with clear urine, atony, retention, thin-walled bladder, dilated ureter, and a kidney which was damaged as regards its vitality.

The third, or bacteriological, part of the paper was based on observations conducted by Professor Dunham, of the Bellevue Hospital College, under Dr. Keyes's direction, with the object of determining the destructive or inhibitive power over the three bacilli under consideration, of a great variety of medical substances often used for local antiseptic purposes in the treatment of vesical suppuration, and also of a variety of urines medicated by the ingestion of a number of different drugs. Altogether, five thousand tubes were examined, and these conclusions were generalized and tabulated. The result was that he showed theoretically what drugs possessed the greater value under varying conditions, *i.e.*, those of direct infection by the surgeons, the tissues not being involved, and those in which, chronic suppuration already existing, the bacilli were protected from the action of the antiseptic. A special effort had been made to reproduce in the laboratory as nearly as possible these conditions, and the results had been very suggestive. The method really consisted in comparing the action of the same drug upon bacteria in group No. 1, where direct infection immediately treated was simulated, with the effect in group No. 2, where chronic inflammation was simulated, the bacilli being more or less protected. This investigation showed that nitrate of silver was by far the most reliable agent we possess in counteracting the effect of local contamination, while corrosive sublimate was more reliable in group No. 2, where the tissues were involved. Salicylic acid was shown to be a very reliable antiseptic, and the author proposed a new solution for its more convenient use. He found that boracic acid had but little or no value, in fact being about as good only as common salt. The various medicated urines showed little or no inhibitive power over bacterial growth.

The following were his conclusions: 1. Healthy urine is sterile. 2. Purulent urine was always microbic. 3. Microbic infection took place from within the body by a number of methods in the course of disease; it was often brought about by instrumental manœuvres on the part of the surgeon. 4. The healthy organism and vigorous bladder could cope successfully with microbic infection, and free itself spontaneously or with a little aid, of all damage arising in this way, and showing little or even no inflammatory response. 5. A suitable condition of the patient's soil was essential to the propagation and perpetuation of the inflammatory phenomena upon the urinary tract after microbic invasion. 6. This condition, intensified by traumatism and physical weakness, notably of the degenerative variety, was most intense when there was physical distention with atony, and when the ureters were dilated and the kidneys involved in the changes incident to tension below—*i.e.*, atrophy and sclerosis above, with or without surface catarrh. 7. Under these circumstances pyelonephritis was most likely to declare itself as a result of microbic infection from below (occasionally from above) in the course of suppurative disease. 8. Asepsis, antisepsis, and sterilization of the urine were ends to be arrived at in genito-urinary surgery, but, like all other greatest goods, was not yet attained in perfection. He thought much, however, could be done by local means in a prophylactic and curative way; little by medication; and possibly as much or more than by any other means, by flushing the urinary passages with natural mineral waters.

The Bacteriology of Pyelonephritis.—DR. GEORGE N. STERNBERG, Surgeon General U. S. A., then followed with a paper on this subject. He said that ascending nephritis or pyelonephritis was very commonly secondary to a cystitis of long standing. Recent researches showed that the bacillus coli communis was found more frequently than any other micro-organism in the so called "surgical kidney." This bacillus was now known to be the cause of peritonitis. It had been obtained in a number of pure cultures, in a number of cases of abscess of the liver, from urinary abscesses, and from the pleural cavity in cases of pleurisy. Injections of a pure culture made into the ureter after tying it below the point of injection, had been shown by Schmidt and Aschoff to give rise to pyelonephritis, and the changes thus induced were said to correspond with those seen in the "surgical kidney" of man. Clado, in 1887, Albarran and Hallé, in 1888, and Rovsing, in 1890, had described non-liquefying bacilli found by them in the urine of cases of chronic cystitis and of pyelonephritis, which appeared to be identical with the bacillus coli communis, and which had been shown, by the subsequent researches of Schmidt and Aschoff, and others, to be very variable in its growth on various culture mediums. Upon gelatine the growths are sometimes transparent and sometimes opaque. Krugius, in 1891, first identified the bacillus described by Clado (his "bactérie septique"), and by Albarran and Hallé ("bacille pyogène"), with bacillus coli communis; and this identification was verified by the researches of Achard, Renault, Schmidt and Aschoff, and others. In twenty-two cases of cystitis studied by him in 1892, Krugius obtained bacillus coli communis fourteen times in pure cultures. Reblaub, in 1892, obtained the same bacillus in pure cultures in six cases out of sixteen cases of cystitis which he examined. The number of cases of pyelonephritis reported by various authors since 1889, in which bacillus coli communis was found and was probably the cause of the ascending nephritis, were twenty-nine; and in twenty of these it was found in pure cultures. The etiological relation of this bacillus to ascending nephritis, the speaker said, seemed extremely probable in view of the fact referred to. Certain cases appeared to be due also to the presence of one or more species of proteus, and possibly to other micro organisms.

Dr. George Chismore, of San Francisco, continued the discussion. He said that the conclusions which he had drawn from his own experience agreed very closely with those given in the paper, yet he differed from the author in some respects. Instead of stone in the bladder being so frequently the cause of nephritis or rendering instrumentation so likely to set up an ascending nephritis, it had seemed to him that under certain circumstances the very reverse obtained. A small stone, growing slowly, seemed to establish a tolerance in the bladder. It had also seemed to him that the introduction of an instrument into the bladder in the young had been more liable to be followed by renal mischief, more particularly of an acute inflammatory character, than in the old subject. Where there was polyuria, with urine of low specific gravity, the danger of instrumentation, as the author had said, was greatly enhanced. The method of attacking microbes by injections into the bladder had seemed to him confessedly faulty, for they certainly could not reach many portions, and the distention and shock connected with the process were not themselves devoid of danger. Moreover, it was often not easy to diagnosticate tubercular affections of the genito-urinary tract, and it was now pretty well understood that when there was a tubercular element the danger of instrumentation was greatly increased. The use of even very dilute solutions of bichloride of mercury seemed to him a means in itself of inflicting traumatism.

Dr. Francis S. Watson, of Boston, said he would refer more particularly in his remarks to the effect of long-continued drainage of the bladder on relieving this form of pyelonephritis. Mr. Reginald Harrison, in a communication published some years ago, had urged this subject upon the attention of the profession. The speaker recalled six cases occurring in his own experience in which pyelonephritis had been greatly benefited by the use of prolonged drainage of the bladder with this particular object in view. These patients were all over sixty years of age, were subject to senile hypertrophy of the prostate, and all their lives were in danger from pyelonephritis. In four of these cases the disease was in the acute stage, and in two in the chronic stage. In four of them the disease had supervened quite suddenly, although catheter life had been instituted a considerable time before. Two of the cases were treated by means of a catheter passed from the meatus, and four of them by a soft-rubber drain introduced through a perineal opening. In everyone there was that most important symptom already referred to—polyuria—with urine of low specific gravity, and the first sign of improvement in these cases was a diminution in the quantity of urine and an increase in its specific gravity. The class to which he thought this treatment especially applicable was in old prostatics, in whom the disease was already well marked or evidently on the point of developing. No one need hesitate to do this operation because of the acuteness of the symptoms. He had had a patient wear a perineal tube, and go about for three years with entire comfort.

Dr. Keyes, in closing the discussion, said that he had emphasized the statement that the bladder was the guardian of the ureter. He was entirely familiar with the method of practice advocated by Dr. Watson, and had practised it with satisfaction. A certain amount of good was obtained in cases of stagnant bladder by the repeated use of the catheter, and still more by drainage through the urethra and perineal opening. The surgical kidney might occur spontaneously. It was an ascending nephritis, rarely a descending nephritis.

The remainder of the session was under the direction of the American Gynecological Society.

The Conservative Surgery of the Female Pelvic Organs was the subject announced for discussion. Dr. William M. Polk, of New York, opened the discussion. He said that his remarks represented an experience with one hundred and sixty-four cases of abdominal section for disease of the appendages. Of this number, sixty-four had been operated upon by the radical process, and one hundred by the so-called conservative process. These cases were taken almost entirely from his hospital practice during the past three and one-half years. There was a lack of unanimity among operators regarding operative procedures on the cervix. In general it might be said that repair of the cervix was preferable to amputation, except in certain cases of hypertrophy or hypertrophic elongation. Among operations on the uterus he would mention three: myomectomy, ligation of the arteries for fibroma, and curettage in all forms of endometritis, whether acute or chronic, puerperal or non-puerperal. The first operation was a promising candidate for popular acceptation. All pedunculated fibroid, fibro-cystic or myomatous growths were favorable for myomectomy. There might, however, be so many such growths as to nullify any attempt at conservatism. The myomata usually had such broad connections with the uterus as to render the operation unsafe. On the other hand, pedunculation and fibrous encapsulation were favorable to the operation.

Ligation of the arteries in the broad ligaments was designed to check the growth of fibroids and the attendant hemorrhages. The operation consisted in a ligation of one or several of the feeders of the uterus, leaving one or more free, according to the exigencies of the case. It appeared to fulfil its purpose as well as, and perhaps better than, oöphorectomy: but our knowledge in regard to it was not yet sufficient to permit us to make any very positive statements.

Curettage and gauze-packing were appropriate in all forms of endometritis, and the most striking results were obtained in the face of acute septic inflammation of the uterus occurring after abortion or labor. Whenever there was any degree of congestion of the uterine wall there was need for depletion, and this could be best effected by the gauze-packing, for it excited uterine contractions, and this affected the circulation in the organ. The operation was a positive advance in treatment, and one which would hold a prominent place in gynecological procedures. It was in the earlier phases of salpingitis and oöphoritis that this treatment showed its best results. Most of the so called cases of recurrent salpingitis, and all of the cases of persistent endometritis, were appropriate for this treatment. Drainage was as useful in inflammation of the uterine appendages as in inflammation elsewhere. Until recently, the speaker said, each one of the following conditions had been considered sufficient ground for the removal of the organs: catarrhal and parenchymatous salpingitis, pyosalpinx, and hydrosalpinx; for the uterus, peri-oöphoritis, ovaritis, ovarian abscess, or purulent inflammation and hæmatoma of the ovary; and adhesions and loculi of pus in the parenchyma proper. He believed that in cases of destructive inflammation the interests of conservative surgery would be best subserved by operating soon after the occurrence of the inflammation. To avoid the occurrence of atrophy of the genital organs in women under thirty years of age, and to retain for them the function of menstruation and ovulation, he had practised resection of the ovaries. In the past four years he had operated upon forty-five patients, and they were in as good condition as any forty-five of ovariotomy that he had ever seen, and mentally they were far better. He had operated on thirty six cases in which the ovaries were the seat of simple cysts, and in all but five the result had been satisfactory both to the patient and to himself.

In conclusion, the speaker referred briefly to a few cases illustrating the occurrence of pregnancy after the practice of this conservative surgery. In reporting these cases he did not mean to be understood that this is the crying issue in this matter; it was rather the mental and moral and physical influence resulting from the preservation of the ovaries.

Dr. William Goodell, of Philadelphia, being too ill to continue the discussion in person, his paper was read by the Secretary.

In his experience few women had perished from

chronic disorders of these organs, even when pus was present. More women died from the radical operation than from the disease itself. Many of these women had been cured by curetting and draining the womb; others he had seen to get well by the use of rest, massage, electricity, alteratives, and by local applications, even when they had been sent to his private hospital to have their appendages removed. In a few instances among his own patients this treatment had been followed by conception and pregnancy. If it became absolutely necessary to resort to operation, then, as little as possible of the appendages should be taken away. If the tubes and ovaries were simply adherent, and not otherwise damaged, they should be merely freed from their adhesions. If they were diseased, only the unhealthy portions should be exsected. He had found that a small piece of an ovary not larger than a bean was ample enough to maintain intact menstruation and sexual feeling. The aim of modern surgery was conservation, yet the glamour of success in antiseptic surgery had so dazzled the modern gynecologist as to make him a spoiler rather than a conservator.

Dr. Luteau, being invited to participate in the discussion, said that he was decidedly of the opinion that a woman under forty years of age enjoyed better health when the function of menstruation was intact. He had never seen Dr. Polk's method of curettage and packing cure a case of pyosalpinx, but he had seen pregnancy follow such treatment.

Dr. Matthew Mann, of Buffalo, said he was very glad that these cases had been brought before the general profession in this way because there was a general idea abroad that gynecologists were a sort of animals who went around with knife in hand looking for opportunities for removing ovaries. It was seen, however, from what had been said in this discussion that the leaders in gynecology did not hold these radical views. He was entirely in harmony with the methods and conclusions of Dr. Polk. He had had women, whom he had treated in this conservative manner, express their gratification to him because he had preserved them from unnecessary mutilation.

Dr. Joseph Taber Johnson, of Washington, D. C., said all were conservative to a certain extent. He thought the radicals would object to have it stated for them that they believed in the total destruction of the woman's genital organs, and in that crowning glory of womanhood—motherhood. He did not know any operator who cut out the ovaries for the cure of a salpingitis, or removed the tubes for a slight inflammation, and where the tube was still patent. Most of the cases operated upon had been already rendered sterile by disease. It was quite likely that the inflammatory process would be set up by the operation itself, and that the last stage of these patients would be worse than the first. Secondary operations were very likely to be demanded after this so called conservative method of treatment. He feared that one result of this discussion would be to return the laity to the position in which they had unfortunately been for ages past, and that many cases really requiring operation would not come to the gynecologist in time for successful treatment.

Dr. Howard A. Kelly, of Baltimore, said that conservation was a better term than conservatism. This discussion had begun ten or eleven years ago at a time when the question of removing both ovaries when only one was diseased had come before the profession. By a study of Sir Spencer Wells's one thousand cases he had found that by leaving in one ovary two hundred and fifty children had been born; about thirteen had had recurrences of the disease, and two women had died. It had formerly been the practice to remove an ovary if a cyst the size of a lemon was found; now we knew that many of these were cysts of the corpus luteum, and they were simply punctured, the ovary not being extirpated. He thought Dr. Polk spoke too confidently regarding the nature of pathological lesions, for we were often unable to determine the exact lesions until the abdomen had been opened. In all cases where there was no inflammation he believed in leaving sound ovarian structure, but where there was such inflammation he thought we would often regret leaving ovarian structure.

Dr. Florian Krug, of New York, said that Dr. Johnson spoke as if there were two camps—the radical and conservative camps. Personally, he felt that he belonged to both camps. He knew of seven cases in which pregnancy had followed partial removal of the adnexa.

The President's Address.—Dr. Alfred L. Loomis, the President of the Congress, delivered his address on the evening of May 31st. The theme was "The Influence of Animal Experimentation on Medical Science." He said that from the beginning of history to the present century medicine had been either absolutely denied a place among the sciences or else branded as inexact, empirical, and laggard in its development and progress; yet to it alone the answer "We do not know" had been denied it. It was possible by experiment alone under control conditions to prove that no involved force had been overlooked, and that the premises were true, and the conclusions in a given case therefore legitimate. The scientific experimenter sought for truth, and truth alone. The science of medicine either stands still or investigates the mysteries of life while its myriad forces were held in perfect harmony; in other words, experimentation must be upon the healthy organism. In widespread epidemics the effect of disease was noticed on perhaps a million of human beings, and with a great sacrifice of human life; whereas in the laboratory great truths were discovered with but small loss of animal life. Every distinct advance, every established principle, and every universally accepted law of medical science had been in the past, and would be in the future, the direct, if not the immediate, result of animal experimentation.

The result of experimentation on animals within the present century had done more than all the experience of previous centuries to raise medicine to the dignity of a science, yet Galen might be said to have laid the foundation-stone of medical science. He showed that the arteries contained blood, that the lung followed passively the movements of the chest, and that the diaphragm, though important, was not the only muscle of respiration. He also demonstrated the nervous control of the voice and explained the mechanics of respiration. In addition to this, he demonstrated the movements of the stomach and intestines and laid the foundation of our present extensive knowledge of the functions of the brain and spinal cord. It was only these portions of his vast labor that had stood the test of modern scientific investigation. From Galen's time to Harvey's great discovery very little experimental work was done, and medicine, instead of advancing to a science, became the plaything of theorists and impostors. Harvey, in 1620, established his great doctrine of the circulation of the blood.

The next series of epoch-making experiments on animals was made by Galvani and Volta, in regard to the condition of the nerves and muscles. The first attempt to continue life for any length of time by means of artificial respiration had been made by Robert Cook, in 1664. This method was now the recognized means of preserving life in cases of asphyxia and in resuscitating the newly born. Boyle, near the close of the seventeenth century, showed that atmospheric air was necessary to animal life. Dr. Christopher Wrenn, of Oxford, was the first to make experiments on injecting substances into the blood-vessels. In 1866 the first transfusion of blood was made in animals. Mr. Boye afterward elaborated this method and showed that death from hemorrhage might be prevented by transfusion of blood. Bell, while experimenting on the facial nerve, established the important fact that the seventh cranial nerve was a nerve of motion and that the fifth nerve was one of sensation. This discovery had been fruitful of practical results both in medicine and surgery.

The great investigations of Magendie on living ani-

mals inaugurated the great work of the present century. The love of knowledge for its own sake was the sole motive of his work. He maintained that the science of life necessitated animal experimentation. By division of the anterior and posterior nerve-roots he demonstrated the existence of motor and sensory fibres. The impetus thus given to the study of the nervous system can hardly be fully appreciated. In addition to this, Magendie established methods of experimentation on the action of medicinal agents, and he was the first to demonstrate conclusively that poisons acted on the spinal cord through the circulation and not through the lymphatics and nerves. We might rightly regard him as the originator of the modern system of animal experimentation. Claude Bernard followed these experiments of his great teacher, and was able to demonstrate that the size of the blood-vessels was under the control of a particular set of nerves.

The speaker said that he would direct the attention of the opponents of animal experimentation to the fact that in all this list of investigations not a single experiment was directed immediately to the discovery of a cure of disease, but solely to the determination of the physiological function and normal action of the vital processes, and to defining the specific influences of given substances on the healthy living organism. The practice of medicine was not by instinct, but by the application of principles. It was not until Claude Bernard applied his experimental methods that the actions of medicinal agents were well understood. It was by such experimentation that modern therapeutics was emancipated from the bondage of empiricism, and no longer wounded friend as well as foe by aimless blows in the dark.

It was worthy of note that all these various investigators were working in one direction—the relief of human suffering. Hunter first learned by experiment on the lower animals that the growth of bone took place from the exterior; subsequently it was discovered that new bone would be developed from the periosteum after the removal of bone. This inaugurated a new era in surgical procedures. The anæsthesia of chloroform was discovered through experimentation on a low form of animal life—the ant. The illustrious Simpson perfected his experiments in the use of chloroform on animals before trying it on the human subject. Hypodermic medication was used on sporting dogs before it was attempted on the human being. All the steps which were necessary to perfect Ambrose Paré's discovery of the application of the ligature on arteries were done on animals. The practical surgeon of to-day values even more highly than these great discoveries the antiseptics which have done so much for modern surgery.

It was, indeed, a significant fact that etiology, which should naturally come first in the study of disease, had hitherto kept in the rear, because it must depend entirely upon animal experimentation for its advancement. Trichinosis was discovered by investigation on animals. It was by laboratory experiments that it had been first proven that tuberculosis was an infectious disease. The valuable studies of Pasteur had introduced us into a new and strange world. No work had ever promised greater results than his. His methods of experimentation had been imitated by investigators all over the world. The crowning glory of Pasteur's work came with the discovery of the attenuation of bacteria. It was not possible to point to work of richer or grander promise, yet it was only possible by experiments on living animals. The time had arrived, the speaker said, when abstract principles were bearing fruit in the prevention and cure of disease.

The discovery of the bacillus of tuberculosis by Koch marked another great epoch in medical history, and it was only accomplished by a continuance of Pasteur's methods of animal experimentation. The light that flashed from Koch's laboratory was the dawn of hope that was already breaking into day when we would hold in our grasp the means of preventing and curing tuberculosis.

Within the past two decades animal experimentation had accomplished more in the field of cerebral localization than in all previous centuries of post mortem study. Looking back over this history of medical discoveries it was evident that most of them had been barren of immediate results. The fatal error of the opponents of animal experimentation was that they demanded immediate results. The only ethical question was, What price should be paid for the benefit received? In the conflict with physical evil, medical science must be the first to meet the foe. No attempt had been made in this address, the speaker said, to conceal the precise methods of investigation. The question was, Does the end justify the means? In answer to this we could fearlessly appeal to all intelligent men for a just criticism. From the ignorant we need expect to receive only censure; but from those who in the valley of the shadow of death had learned what manner of men we were, we could confidently expect the answer, "We have trusted to you the lives of our dear ones; we trust to you God's dumb creation."

Fourth Day, Friday, June 1st.

The first part of the session was under the direction of the American Laryngological Association.

The Surgery of the Accessory Sinuses was the subject announced for discussion. Dr. F. H. Bosworth, of New York, opened the discussion. He confined his remarks to a consideration of ethmoidal disease. He said that while in dealing with these cavities it was only necessary to make an opening for proper drainage, in dealing with disease in the ethmoidal cells, especially where suppuration had taken place, an opening in each of the large number of small cells was requisite. But this was only possible by breaking these down into one large cavity. Ethmoidal disease set up a train of symptoms more or less neurotic in character, such as watery discharge from the nose, sneezing, neuralgias, asthenopia, and especially a peculiar condition in which the sufferer found it impossible to fix the mind upon any subject. He believed a very large proportion of cases of supposed acute rhinitis were really instances of ethmoidal disease. In a previous paper he had described five varieties of diseased conditions of the ethmoidal sinuses. Rhinoscopic examination in the inflammatory stage of the disease showed the middle turbinated body as a rounded mass encroaching upon the middle meatus of the nose. The ethmoidal cells he considered part and parcel of the turbinated bodies. The inflammatory process within the cells resulted in hypersecretion, which materially contributed to the intra-cellular distention and in a closure of the normal orifices. This led to the formation of an abscess. As a general rule, where there was a chronic inflammation of a mucous membrane in a closed cavity the tendency was to abscess formation. A "dropping in the throat" should suggest the possibility of an empyema of the sphenoidal or ethmoidal cells. As a result of persistent suppuration the lining membrane of the cells became softened. He did not attach much importance to the use of the probe in diagnosis, as he depended chiefly on the appearances about the middle turbinated body. The deceptive sense of necrosed bone could be obtained by passing a probe either below or above the middle turbinated body. He favored the use of the douche—one to two gallons of saline water being passed through the nasal cavities by the Thudichum douche at least twice daily, using the water as hot as could be borne. There was no danger of exciting ear trouble if the patency of each nostril were tested previously and the stream made to enter through the narrowed nares. After the occurrence of pus formation the cells must be broken down into one large cavity and drainage established. The cells should be uncapped by means of a snare, and then the dental burr should be used. He had never been able to freely manipulate the curette in the ethmoidal cells. In many cases it was necessary to re-

peat the operations many times over a period of perhaps a month.

Dr. J. H. Bryan, of Washington, D. C., continued the discussion. His remarks were limited to the surgery of the maxillary sinuses. As the indications for the treatment of mucocele and empyema of the maxillary sinus were the same, he wished his remarks to be taken as referring to the latter condition. Empyema of the maxillary sinus was formerly considered a condition of rare occurrence, but now it was known to be of frequent occurrence, and that marked distention of the walls of the sinus was rarely met with. Cysts and other tumors of the antrum were included in the older descriptions of empyema of this cavity. In the majority of cases it might be necessary to make an artificial opening into the maxillary sinus. Up to 1876 there were three methods of opening this sinus. If there were carious teeth present, and there usually was, they should be extracted. If the cavity were not opened by this procedure, communication would have to be established by means of a small trephine propelled by a small motor. The cavity should be perforated at its most dependent part and the opening made sufficiently large to admit of the passage of a small metallic drainage-tube about three millimetres in diameter. This procedure secured excellent drainage, and the patient could carry out a large part of the local treatment. The objections were that a sound tooth might have to be extracted, and that pathogenic germs might pass from the mouth into the cavity and infect it. If it were desirable to enter the cavity through the nose, then some modification of the Mickulicz method should be adopted. A curved trocar should be introduced along the floor of the nasal chambers, then turned outward, and made to perforate the inferior meatus into the cavity. This was not practicable if the nasal chambers were very narrow, or there was marked hypertrophy of the inferior turbinated body, and it had the disadvantage of requiring all the applications to be made by the surgeon himself. In recent cases the intra-nasal operation possessed many advantages; for other cases the alveolar method was more suitable. After opening the cavity it should be frequently washed out with a mild antiseptic solution. The irrigations might be made through a Eustachian catheter, the cavity being filled to its fullest capacity. The simpler and less irritating the application, the more readily would the secretion subside. Owing to the irregular shape of the cavity it was impossible to thoroughly distribute powders over its walls.

The speaker said that he had adapted the endoscope to these cases, and by its aid the cavity could be inspected. Such inspection would frequently show the cause of persistent suppuration. Polypi, supernumerary teeth, necrosed bone might be found to be the cause of the chronicity of these cases.

Benign tumors of the maxillary sinus were comparatively common, although up to a dozen years ago they were considered to be decidedly infrequent. These tumors might consist of cysts, polypi, osteomata, and fibromata. Among the malignant growths found here were epithelioma, carcinoma, and sarcoma.

Dr. J. N. Mackenzie, of Baltimore, said that very little advance had been made for ages in the surgery of the accessory sinuses. The interesting part of the subject under discussion centred upon the manner of reaching the interior cavities. There were several ways of opening the antrum, as had been described by the last speaker. The natural opening to the antrum was not only difficult of access, and painful in spite of the use of cocaine, but the subsequent syringing, which often required to be continued for many months, was also painful. In addition to this it was difficult to secure a free outflow of pus through the naso-antral opening. It had been proposed to remove the middle turbinated bone as a preliminary step, but this procedure did not seem justifiable as long as other methods were at our disposal. It had also been proposed to make an opening through the inferior meatus just below the normal opening, but it was a difficult procedure, and was sometimes attended with quite free hemorrhage. Moreover, the antrum was occasionally so thick at this point that it was impossible to penetrate it with a spear-shaped knife of Mickulicz. It should be noted just here that this instrument was not well suited for this operation; the drill was preferable. Entrance to the antrum through the canine fossa should only be attempted where there were growths in the antrum, or where the walls of the antrum were exceptionally thin. In his opinion the best way of gaining entrance to the antrum was through the tooth. Its greatest advantage was that it secured absolutely perfect drainage, there being a counter-point of drainage through the nose. It had been objected that this operation might involve the loss of a sound tooth, but he did not think anyone would prefer to keep a tooth and lose the middle turbinated bone. The tube could be readily plugged if one feared the entrance of food into the cavity, but as a matter of fact food did not generally gain access to the cavity even when this precaution was not taken. Sometimes a contra indication to the operation would be found in the fact that the bone of the alveolar process would be so very dense that it would be extremely difficult to drill it.

Before operating on a case of ethmoidal disease it should be recollected that where the disease was due to a polypus sufficient time should elapse before operating to be sure that the symptoms would not disappear without further interference.

Dr. John O. Roe, of Rochester, said that the treatment of disease of the accessory sinuses was largely surgical, owing to the irregularity and inaccessibility of these passages. The diseases of these sinuses should be divided into acute and chronic.

The chronic form included empyema, mucocele, tubercles, and growths of nearly every variety. The acute diseases rarely required surgical interference. Empyema from these cavities should be looked upon as a symptom rather than a disease. What was often called was, in his opinion, nothing more than a fetid discharge from an untreated disease of the accessory sinuses. Several cases were cited to illustrate certain points in diagnosis and treatment.

Successful treatment depended on a correct understanding of the seat of the disease and of the pathology. If there were no history indicating disease of long standing, he would begin the treatment usually by injections through the natural passage. When catheterization was impossible, an artificial opening should be made through the socket of a carious tooth, or if the tooth were sound, through the zygoma. If the disease did not readily subside, an opening should be made into the zygomatic fossa and necrosed bone removed.

The remainder of the session was under the direction of the American Neurological Association.

The Influence of Infectious Processes on the Nervous System was the subject for discussion. Dr. James J. Putnam, of Boston, discussed the pathology and etiology. He said that the relation of nervous diseases to infectious processes might be studied from the point of view of the bacteriologist or the neurologist. The infectious diseases which would be generally admitted to cause nervous affections were tetanus, rabies, syphilis, tuberculosis, diphtheria, lepra, gonorrhœa, typhoid, erysipelas, influenza, mumps, the acute exanthemata. the pyogenic organisms, the diplococcus lanceolatus, malaria, actinomycosis. The nervous affections following acute infectious disease were not always due to the primary infection, but to a secondary infection; or they might be only an indirect result. The diseases of the nervous system which were only so far suspected of being of infectious origin were especially beriberi poliomyelitis, Landry's disease, certain forms of myositis, neuritis, myelitis, some of the cerebral palsies of children, chorea, disseminated sclerosis and other cerebro-spinal and spinal scleroses, amputation neuritis, herpes zoster. Finally, there were various affections following in the wake of infectious processes, but hardly to be classed as indicating the action

of specific virus. Such were the constitutional neuroses and psychoses, the adynamic cerebral affections, the results of œdema or of arterio-sclerosis, various forms of sclerosis of the spinal cord, to which the nervous system was always prone, and subacute forms of multiple neuritis of the ordinary type.

A disease would be suspected to be of infectious origin when bacteria were found in the tissues; when the outbreaks occurred in epidemics, or were related to seasons or localities; when it exhibited vascular and histological changes characteristic of the infection, or specific toxicity of the blood and urine; or if it had become much less frequent since the introduction of antiseptics. The arguments were strong in favor of the infectious origin of the different forms of acute myelo-neuritis or poliomyositis. They were certainly due to powerful poisons acting like bacterial toxines. Bacteria had been found in Landry's disease, but were not yet accepted as specific. Myelitis (acute focal or transverse) could be produced experimentally by infection of cultures, or might even follow gonorrhœa. Acute multiple neuritis might follow almost any one of the infectious processes. The meningitis which followed the exanthemata was probably due to secondary infection. In diphtheria and other affections the virus seemed to be almost the equivalent of the organism in its power of exciting local reaction. The specific organisms liable under favorable conditions to cause meningitis were often present in even the healthy pharynx. If we excluded the cerebro-spinal membranes, which were a great breeding place for many bacteria, we might say that the instances of local bacterial action upon the nervous system were few; while on the other hand, the nervous system was especially prone to suffer from toxic agents circulating in the blood. These poisons were sometimes separable into several definite constituents, which varied as regards their volatility, solubility in alcohol, and their physiological action. Several of them had a strong tendency to attack the vaso-motor system, and by thus disturbing the circulation, to prevent the normal vascular dilatation so necessary for the protection of the body against the invasion of pathogenic organisms. In tetanus, the irritability of the spinal cord was heightened as in strychnia poisoning; in diphtheria the cardiac centres were sometimes strongly involved, though gross lesions might be absent; in influenza the tendency of the poison was toward the brain more than in the case of some of the analogous diseases.

The causes which contributed to increase the liability of the nervous system to suffer from the effects of infectious disease might be divided into, 1, those which increased the liability to invasion of the body by pathogenic organisms; and 2, those which lowered the resistance of the nervous system. Of the latter class were hereditary weaknesses in special directions, the presence of other poisons in the nervous system, the effects of trauma, a poorly acting vaso-motor system. Debility of the nervous system might contribute to increase the liability of the body to invasion, by impairing the vitality of the tissues which should resist the germs of disease, besides impairing the efficiency of the vaso-motor reactions.

The most important lines of research for the future were in the direction of classifying the special liabilities on the part of the nervous system to disease, independently of infectious causes; the refinement of our methods of histological research; the more wide spread and thorough study of bacteriology, and of the means of determining the toxic condition of the blood and urine.

The Relation of Infectious Processes to Mental Disease.—Dr. Charles K. Mills, of Philadelphia, then read a paper on this subject. He said that nearly a century ago Rush had declared that certain causes, as gout, dropsy, consumption, pregnancy, and fevers of all kinds produced madness by acting on the brain, in common with the whole body. Among the questions to be considered were, whether the mental disorders of well-known forms of infectious disease were toxæmic, or were due to anæmia, exhaustion, or other causes; and whether particular types of insanity were due to the action of specific micro-organisms.

Regis and Chevalier-Lavaure, in a report at the Congress of French Alienists in 1893, distinguished mental disorders due, 1, to infectious diseases; 2, to visceral disturbances; and 3, those associated with diathetic maladies. While not denying the origin of mental manifestations, and even special types of insanity, from other causes, such as traumatism, anæmia, exhaustion, and emotional shock, he believed they were sometimes due to the action of infectious and toxic agents, and probably to specific micro organisms, although the last could not be regarded as absolutely proved. The question of febrile delirium, and febrile and post febrile insanity, had been especially considered by numerous observers. A special type of confusional insanity had been suggested as following infectious and diathetic disorders. He could recall one case of acute delirious mania with hyperæsthesia, active contractions, and petechial eruption, in which the symptoms were highly suggestive of cerebro spinal meningitis; but the autopsy revealed nothing, and the case was apparently one of toxæmia associated with anæmia. Many other such cases might be cited.

In considering the analogies with nervous affections, not psychoses or insanities, but which were supposed to be of microbic origin, it was only necessary to refer to such diseases as multiple neuritis, some forms of myelitis, and chorea. The teachings of the recent epidemic of influenza were important in this connection.

Pellagra was a disease, doubtless of infectious origin, with marked nervous and mental manifestations associated with lesions of the skin, and in which pathological and microscopical investigations showed combined lesions in the lateral and posterior regions of the spinal cord.

One of the most valuable contributions on the etiology and pathogenesis of acute delirium had been furnished by Rasori, who had described in detail a case of acute delirium with autopsy, and the results of a careful bacteriological examination. The autopsy was conducted with the strictest bacteriological precautions. Two inoculations with subdural fluid led to the development of the same micro-organism. A series of inoculation experiments on rabbits then demonstrated that the bacillus obtained from the subdural fluid produced a toxic substance which destroyed the rabbit with symptoms of septicæmia in a short time.

The toxæmia of pregnancy and the puerperal state sometimes result in a mental disorder. Tuke and Woodhead believed that a considerable proportion of cases of puerperal insanity were due to toxic influence without reference to childbirth, and Olshausen observed eleven cases of psychoses following eclampsia, out of a series of two hundred cases observed. Gerdes had claimed that the eclampsia bacillus was the sole cause of puerperal eclampsia, and that this organism was found in no other disease.

The following are the author's conclusions: 1. Specific infection must be included among the causes of the mental symptoms and disease which precede, accompany, or follow febrile and other infectious disorders, though other causes are sometimes active. 2. Much negative evidence can be adduced in favor of acute delirium or acute mania being due to toxæmia, such as is afforded by autopsies. 3. Analogies with nervous affections which are known or believed to be of microbic origin favor the view that insanities with similar or related phenomena and lesions are also microbic in origin. 4. The evidence afforded by careful bacteriological investigation of cases of acute insanity is thus far meagre, and seems to show that various micro-organisms may induce the same or similar types of mental disease. 5. The mental disorders of pregnancy and the puerperal state are probably, in a considerable proportion of the cases, toxæmic, without reference primarily to childbirth; but it cannot be regarded as proved that a bacillus of either

eclampsia or puerperal mania is the sole cause of these affections.

Dr. F. X Dercum, of Philadelphia, closed the discussion with a few remarks on the therapeutics of this subject.

AMERICAN GYNECOLOGICAL SOCIETY.

Nineteenth Annual Meeting, held at Washington, May 29, 30, and 31, 1894.

William T. Lusk, M.D., President, in the Chair.

First Day, Tuesday, May 29th.

Address of Welcome.—The President, Dr. Lusk, called the society to order at 10 A.M., and introduced Dr. Fry, who read a brief address, heartily welcoming the members to Washington.

Extirpation of the Uterus in Disease of the Adnexa.—Papers in the affirmative upon this subject were read by Drs. J. M. Baldy, Florian Krug, and H. T. Hanks; in the negative by Drs. W. G. Wylie and B. McE. Emmet.

Dr. Baldy read the first paper. The discussion of the extirpation of the uterus in disease of the adnexa would, he said, be confined principally to the pelvic inflammatory diseases, conditions being considered secondarily for the reason that this procedure would be called for mostly in the former class of affections.

Certain general considerations arose in this connection: 1, Is the uterus essential or useful after the ovaries have been removed? if not, *a*, Are all patients cured after an operation requiring double ovariotomy? *b*, Are patients cured after hysterectomy when double ovariotomy has failed? *c*, Does the operation of hysterectomy increase the mortality above that of double ovariotomy? *d*, Is the retention of the uterus any disadvantage or danger to the patient? In reply to the primary question, Is the uterus essential or useful after the ovaries have been removed? the reply was that the uterus has one use in the body, that of containing and developing the human embryo. In the face of the loss of both ovaries it seemed to the reader superfluous to argue that further necessity for this organ had departed, and together with the necessity its usefulness. It was not true, as had been held, that the uterus had anything to do with those peculiarities which went to make up the womanhood of woman; this rested solely in the ovaries. Nor was it demonstrable that this organ had anything whatever to do with the integrity or support of the vaginal vault; as far as the cervix being the keystone to the vagina was concerned there was no necessity for removal of this structure. His own experience taught that there was less sagging of the pelvic floor in those cases in which the uterus had been removed than in those in which simply a double ovariotomy had been performed.

The proposition, Are all patients cured after an operation requiring double ovariotomy? was answered in the negative by a common and universal experience. Many patients returned suffering from pain, metrorrhagia, or discharges of muco-purulent matter from the uterus.

Proposition *b* could be answered only by experience. In four cases in which the patients continued to suffer after removal of the appendages he subsequently removed the uterus, with cure. In one local treatment was tried without for a year removing the uterus.

Regarding proposition *c* he had found hysterectomy with removal of the appendages less dangerous than double ovariotomy in similar conditions, while convalescence had been infinitely smoother and more satisfactory.

Regarding the question, Is the retention of the uterus of any disadvantage or danger to the patient? Dr. Baldy reminded his hearers of the fact that it not infrequently bled, was the seat of muco purulent discharge, caused sagging of the pelvic floor, was liable to undergo tubercular or malignant degeneration. It had been contended that twenty per cent. of all cases of pus tube were of tubercular origin, and a large proportion of uteri were also infected in such cases.

Where the womb was greatly enlarged, infiltrated, or diseased, it was proper to remove it; also where there was good reason to believe it would in future become the seat of disease; where its removal would facilitate an operation or give greater security against hemorrhage.

It was assumed, however, that both ovaries had to be sacrificed. It must not be understood, Dr. Baldy said, that removal of the uterus with the tubes and ovaries was recommended in all cases of pelvic inflammatory disease. He concluded by giving reasons for preferring the suprapubic method.

Dr. Florian Krug read the second paper. We were now in a position, he said, to accurately estimate the benefits derived from the old operation of removal of bilateral purulent disease of the appendages, and to say in how far the operation had failed. Careful observation, devoted to cases for some time, demonstrated that while pathologically they were cured, but few were symptomatically relieved. The cause of the failure rested in not removing the original persisting source of infection, the uterus. Either the cases operated upon by those who claimed that the uterus, when left, was not a cause of further symptoms, and might be rendered innocuous by mild treatment, were not thus cured, or else the gentlemen making these statements had submitted to their skill the most simple cases, as a rule, and in the severe ones had failed to observe the results of their work. The cause of continuance of distressing symptoms was the primary lesion in the uterus; the effect of the premature menopause upon the sympathetics; the irrregular and delayed involution of the uterus; the adhesions formed between the intestines and raw surfaces in the pelvis; the possibility of repeated infections of the uterus, of ventral hernia, owing to the different methods of drainage; and many other lesions and malpositions natural to the uterus, repeatedly inflamed and deprived of its supports. Broadly stated, a continuance of the symptoms is due to retention of the inflamed uterus, which is the primary seat and original cause of every lesion found in these cases, and the effects of its continued influence upon the pelvis, lymphatics, and nerves.

Dr. Krug related some cases, and then said: Such a study substantiated me in the belief and confirmed me in the method I now employ in every case demanding the sacrifice of both adnexa, removing the uterus also. The following reasons appealed to him: The uterus without the adnexa is a useless organ and devoid of physiological function. It is not innocuous; it is, on the contrary, positively a diseased and therefore harmful organ. Histologically the tubes are but parts of the uterus, and their removal is partial amputation of the uterus; therefore, why should we not go a step further and remove the rest of the diseased organ. Is it conceivable—clinically, is it a fact—that those projections of the uterine tissue which we call the tubes are alone diseased, and not the rest of the uterus?

Leaving the uterus merely invited future infection. Did removal of the uterus involve increased danger, some objection might be made to it, but it did not. On the contrary, it lessened the mortality in the hands of those familiar with the technique of hysterectomy.

That I may not be misunderstood, in closing I will emphasize the fact that I am dealing only and solely with those lesions of the adnexa where both are the seat of disease precluding the possibility of cure by all conservative methods.

Dr. H. T. Hanks, of New York, read the third paper. Formerly when patients continued to suffer after he had removed the diseased appendages he had tried to explain the fact on the supposition that he had not made a complete operation; but on further observation he became convinced that this was not the case, at least not often in his practice. Where the uterus was safely removed with the adnexa the patients, he believed, would have greater security against troublesome after-symptoms. Drainage

through the vagina was obtained and constituted the ideal drainage; nearly every patient convalesced without complications. One should not, however, urge removal of the tubes and ovaries and with them the uterus, unless there were evidences of permanent lesion causing the symptoms from which the patient complained. The vast majority of cases of catarrhal salpingitis could be cured without operation.

There were three conditions falling properly under the subject for discussion in which Dr. Hanks thought the uterus should be extirpated in connection with the appendages. First, in old pyosalpinx, with much exudation and purulent endometritis, or chronic catarrhal endometritis. Second, in puerperal salpingitis and ovaritis and probable puerperal endometritis, without evidence of drainage into the uterus. Third, if in removing the ovaries and tubes many adhesions were broken up, the uterus being retroverted or retroflexed and held down.

Dr. Bache McE. Emmet was called upon to read the first paper upon the negative side of the question. His remarks were more especially in reply to points made in the discussion before the New York Obstetrical Society, October 3, 1893, Dr Polk and Dr. Krug having taken the affirmative view on that occasion. Were we, he said, to include in our scope the much larger question, "hysterectomy for suppuration within the pelvis," we would open up quite another line of thought, one which had been well explored. In France, Germany, and Belgium, this operation had won a place.

To revert to our more limited area of thought concerning the question of removal of the uterus with the appendages, once we have opened the abdomen and found the latter diseased so that they call for complete removal. I say advisedly "once we have opened the abdomen," as opposed to the French school. Dr. Polk insists upon this mode of approach to the adnexa. Finding that we have to remove these in their entirety, he recommends and asks our approval of removal of the uterus in all cases. Dr. Polk does not make the distinction of pus sacs which cannot be enucleated, and in which the advantage of drainage derived from removal of the uterus we can appreciate.

Dr. Emmet went on to give reasons for dissenting from the extreme view of removing the uterus simply because on opening the abdomen it was considered necessary to remove the adnexa.

Dr. W. Gill Wylie opened his remarks with the question, When we remove the Fallopian tubes and ovaries should we remove the uterus also in all cases? If he must answer this question by yes or no he would say no. The uterus should be removed with the tubes and ovaries when there were indications of malignancy, of intractable disease within the uterus, of septic disease, in fibromata, and as a rule when the patient was over thirty-five years of age. In the large majority of other cases where the adnexa had been completely removed, subsequent suffering had been slight. Most of those who had suffered would not had the uterus been divulsed, curetted, and drained before or subsequent to the removal of the tubes and ovaries. According to his limited experience women who had had the uterus removed with the adnexa had had less reflex disturbances such as were common at the menopause in those with uterine disease.

We should not be carried away with our ability to remove the uterus with little more risk than to remove the adnexa alone, and allow ourselves to remove that organ in all cases without particular study of the remote and immediate results after a large experience. Dr. Wylie said he was not willing to assert that even in the fully grown woman removal of the appendages did not after a time cause loss of sexual desire and prevent satisfactory consummation of sexual intercourse. The younger the woman the more marked would be the atrophy of uterus and vagina and loss of elasticity and healthy tone.

Although his first hysterectomy was done twelve years ago, until within a few years his operations had been done almost solely for cancer and fibroma, and with few exceptions in women over thirty, usually over forty, so that he was not prepared to say what were the results of complete removal of that organ. It was, however, attended by possible accidents at the time of the operation or afterwards, which made it more dangerous than simple removal of the appendages when there was no special indication for going further.

Verbal discussion being called for, Dr. Wathen, of Louisville, expressed himself as positively opposed to removal of the uterus unless there were some condition in the organ itself calling for it.

Dr. Byford, of Chicago, thought it absurd to say the uterus should be removed in all instances where it was necessary to remove the adnexa. The two conditions in which the uterus should also be taken out were, 1, where it was safer as an operative procedure than to remove the appendages alone; 2, where the uterus could not be cured without removing it.

Dr. G. M. Edebohls, of New York, thought there was both an affirmative and a negative side to the question. In a nutshell, there were two indications for going on to remove the uterus: 1, where the conditions (pus, etc.) necessitated downward drainage; 2, where the diseased condition of the uterus demanded its removal.

Dr. Cushing thought the views of the speakers not so far apart as appeared. He spoke more especially upon the question of the comparative safety of simply removing the adnexa or removing these and the uterus as well. Only few gynecologists could assert that hysterectomy was as safe; in the hands of the great majority it was a much longer and more difficult and dangerous operation, and in view of the fact that in the class of cases under discussion removal of the appendages alone effected a cure, he would rather limit himself to that procedure.and remove the uterus subsequently if it should prove necessary.

Dr. J. E. Janvrin, of New York, thought the only point which concerned us was what diseases of the uterus, and how much, demanded its removal.

Dr. Gordon, of Maine, thought that if the uterus were healthy and in place, there was every reason for leaving it.

Dr. Noble, of Philadelphia, believed in removing the uterus only in case there was a definite object, as incurable disease of that organ itself. He was opposed to taking it out simply because the tubes and ovaries required removal.

Dr. W. R. Pryor thought few conditions existed requiring removal of the adnexa which did not also call for removal of the uterus, nor would he consider it advisable to leave any of the cervix to complete the vault of the vagina.

Dr. A. P. Dudley thought the papers supporting the view that the uterus should also be removed implied that the authors in the past had failed to cure their patients when they had removed the adnexa for catarrhal salpingitis. He opposed hysterectomy where the uterus showed only a catarrhal condition.

Closing remarks were made by the authors.

The Treatment of Face Presentations.—Dr. Reynolds, of Boston, opened the discussion upon this subject with a paper. The following summary was made: When a face presentation is detected before the engagement of the face and before rupture of the membranes, there is always hope for a spontaneous restoration of flexion. Therefore adopt postural treatment and gentle external manipulations. When the membranes rupture early an external or bipolar version should be performed at once in any case in which the condition of the cervix renders manual dilatation dangerous, but in ordinary conditions manual dilatation should be undertaken, the head flexed by the hand and subsequently the appropriate operation should be performed.

When the membranes persist until the cervix is completely dilated an anterior position of chin should be left to nature so long as its progress is rapid and the fœtal heart

is steady: otherwise the patient should be anæsthetized, and the head flexed. The posterior position of the occiput so produced should not be left to nature, but should be either treated by version or, preferably, rotated to the front. It may then be left to nature or treated by forceps.

Posterior positions of the chin should never be left to nature, but be subject to immediate manual flexation. The anterior position of the vertex which then results may either be left to nature or be delivered by forceps. In neglected cases in which manual flexation is contra-indicated version should be chosen if practicable, if contra-indicated apply forceps to face, but chin should first be front.

In cases in which the face presentation is due to some other mechanical obstruction the treatment should be determined by the latter factor. The abdominal methods of delivery are never indicated in uncomplicated face labor.

Management of Face Presentations.—Dr. Charles Jewett, of Brooklyn, said his views of treatment of face presentations assumed two things: 1, the mechanism of face birth is abnormal and may of itself constitute a serious complication of labor; 2, presentation by the face is more frequently associated with other complicating conditions than are vertex births—*e.g.*, small pelvis, large child, prolapse of small parts.

The mechanism tends to dystocia; complete adaptation of the head to the pelvis is impossible in mento-posterior positions.

More important is the difficulty of rotation. Yet in wholly uncomplicated cases of face presentation spontaneous birth is the rule, although the labor is somewhat longer. The mortality of the children is greater. The graver difficulties of face birth arise chiefly from its complications—disproportion between head and pelvis, prolapse of fœtal members, or failure of pains—anomalies which are much more frequent in face than in vertex presentations.

In treatment cases could be divided into two classes: 1, those in which the head is movable at the brim or can be made so by pushing it up; 2, those in which the head is permanently engaged.

In the first, if the chin were anterior and pains failed, apply forceps. If the head were large, cord or arm prolapsed, version would, as a rule, best serve the interests of the child. Like in the former, if the chin were posterior spontaneous birth was generally possible if other conditions were favorable. He preferred, however, to reduce this presentation to a simpler one, the first choice being as a rule to bring down the occiput. Conversion of face to vertex presentation might be tried after the face had sunk some distance into the pelvic cavity by postural methods. For either correction after engagement or for forceps extraction, Walcher's position might lend important help.

Dr. C. P. Noble, of Philadelphia, said that while he was in accord with the readers of the papers, he wished to suggest the propriety of resorting to symphyseotomy in cases of face presentation, head engaged, waters broken.

Dr. Edward P. Davis, of Philadelphia, continued the discussion with a paper.

Statistics showed the best results to mother and child in spontaneous delivery in face presentations. Methods best adapted to secure this result must be based upon early diagnosis, hence the importance of perfecting the knowledge and practice of palpation. The treatment best adapted to secure spontaneous labor consisted in retaining the membranes unbroken until the time of spontaneous rupture, sustaining the patient's strength, and placing her in posture to favor rotation of the chin anteriorly. With face looking to left side, the mother should lie upon the left side, thighs flexed.

As soon as dilation is complete, the obstetrician is to choose between radical interference by version or an effort by the methods of Bandelocque and Schatz to correct the face presentation by converting it into an occipital one. The choice should depend upon the size of head, pelvis, and condition of pelvic floor.

Before concluding Dr. Davis remarked that obstetricians were familiar with the facility with which faulty presentations could be remedied under complete anæsthesia and with a roomy pelvis in the oblique diameters, and suggested that it might be well to secure these conditions, if absent, by symphyseotomy.

The discussion was participated in by Drs. R. A. Murray, Fry, the President, and others.

Dr. Fry spoke of the necessity for several assistants in order to place the anæsthetized patient in the genupectoral position, and recommended Trendelenburg's over a reversed chair.

Dr. Lusk related a case brought to the maternity after the attending physician had injured the uterus, bladder, vagina, and rectum by trying to deliver by forceps. He then performed symphyseotomy and extracted the child with ease, although, of course, the mother, being already moribund, died.

AMERICAN OTOLOGICAL SOCIETY.

Twenty seventh Annual Meeting, held at Washington, D. C., Tuesday, May 29, 1894.

Brain Abscess.—Dr. Herman Knapp, of New York, presented a report of a case of otitic brain abscess, opening of mastoid, tympanum, and skull, evacuation of abscess, hernia cerebri, evacuation of another abscess, and recovery. The patient was nine years of age and had suppuration of the ear following scarlatina. She presented the aural and general symptoms of confined pus, choked disk in both eyes, more marked in left eye, moderate in right. A diagnosis of intracranial abscess was made. She had well-marked homonymous right-sided hemianopsia. An ice-bag was applied, with cleansing with boracic acid, when the swelling of the right optic disk diminished; no other change. Prognosis, perhaps fatal, and treatment by operation was advised. Two weeks later the right optic disk was normal, left much less choked. The memory, which had before been feeble, was now good; pulse, 120; temperature, 100.2° F.; no swelling over the mastoid, large perforation in the membrana tympani; no dead bone was felt; the tip of the mastoid was tender; MacEwan's symptom was present. The operation was performed the following day, Dr. M. A. Starr being present. Parts shaved and cleansed. The mastoid was of compact texture and normal. The lateral sinus was brought into view, blue and pulsating. Schwartze's modification of Stocke's operation was followed, and when the chisel had opened into both antrum and attic, pus suddenly ceased to flow from the canal. The skin incision was enlarged, skull trephined, and healthy dura incised. A hypodermic needle passed into the brain substance brought pus, which was evacuated through an incision made down to the abscess along the needle; the wound was cleansed with 1 to 5,000 solution of bichloride, drainage-tube inserted, and dressed with absorbent cotton and roller bandage. A hernia cerebri resulted, attaining the size of a goose-egg. No improvement resulting, a second abscess was discovered in the hernia and evacuated, when improvement immediately took place; the hernia disappeared by retraction, and the patient was discharged well three months after.

Dr. Carmalt congratulated Dr. Knapp on the happy outcome and on his skill in the diagnosis of the case. He could add nothing to the discussion, and had nothing but respect and admiration for the way in which the work was carried out.

Dr. B. Alexander Randall spoke of a specimen in a case where, in spite of an existing meningitis, he was enabled to suspect cranial abscess, mainly on account of the behavior of the pulse. On post-mortem examination the whole base of the brain was found covered with

thick pus in which were three abscesses, one on either side of the medulla and the third in the cerebellum.

In answer to a question by Dr. Lucien Howe, as to what symptom made Dr. Knapp believe the child was growing worse, Dr. Knapp stated that the principal one was the behavior of the disks. In brain tumor, the disks are choked equally on both sides; in abscess, more on the affected side.

Dr. W. B. Johnson, of Paterson, N. J., spoke of a case which he had seen in its last stage. The purulent discharge seemed to have come from the lateral sinus to the neck, where there was a large swelling and fluctuation. The autopsy showed a large quantity of very green, bad-smelling pus, mostly on the petrous portion of the temporal bone, and along the base of brain, and a point of perforation between the base and the petrous portion, where it had extended from the attic.

Dr. Bacon spoke of having seen Dr. Knapp's case in company with Dr. Blake, and was very much interested in the result.

Suppurative Otitis.—Dr. F. M. Wilson, of Bridgeport, Conn., read the next paper, reporting five deaths following suppurative otitis and two autopsies. In one there was an erosion downward through the skull along the neck and into the mediastinum and left lung. Practically no cerebral symptoms. Perhaps early removal of ossicles or opening of antrum might have prevented the result.

Case II.—Sinus thrombosis with extension through neck and into lung without pain, tenderness, or tenderness in neck.

Case III.—Some pain in auricle, none in mastoid; later tenderness in neck. Mastoid opened and cleansed, with temporary improvement; then recrudescence, afternoon rise of temperature. Pericarditis; death. No autopsy.

Case IV.—Cerebro-spinal lepto-meningitis. Infection of soft parts.

Case V. was most noteworthy, from the amount of pus found in the neck—about a pint.

Dr. Knapp thought the consideration of indications for operation were very important. He had operated and found no pus, and bone healthy, and had also perhaps sometimes waited too long.

Dr. Randall asked whether there were not clear cases of sinus thrombosis causing septicæmia, which later disappear and recover without operation, and referred to a case published in the *Philadelphia Polyclinic*.

Dr. Wilson replied that in the presence of symptoms of sinus thrombosis, and in view of the quickness it was best to operate quickly.

Middle ear Operations for Improving the Hearing.—Dr. E. B. Dench, of New York City, read a paper on the utility of middle-ear operations as a means of improving the function of the organ. After a general classification of the various procedures, emphasizing the importance of diagnosis, the method employed in locating the lesion in the conducting mechanism was described. The operations receiving particular attention were synechiotomy, removal of the membrana tympani, malleus, and incus, with mobilization of the stapes, and the division of adhesions between this ossicle and the adjacent tympanic walls. Special emphasis was laid upon the operative technique and the advisability of employing local anæsthesia in all cases where the operation was performed for improvement in function alone.

The removal of the stapes, both in the suppurative and non-suppurative cases, had not yielded as uniformly good results as removal of the two larger ossicles and artificial mobilization of the stapes.

In all 63 cases had been operated upon for improvement of the hearing, and in 55 the result had been satisfactory.

Dr. C. J. Blake made some comments on the position of the incision, and the possibility of the view being obscured by hemorrhage if done too hurriedly. The healing is very rapid. In a case where bands about the stapes were divided, when the posterior were cut, improvement of hearing resulted, but afterward when the anterior adhesions were divided the hearing dropped.

Dr. S. Theobald remarked on Dr. Dench's experience with cocaine as a local anæsthetic.

The Foramen of Rivinius.—Dr. B. A. Randall, of Philadelphia, Pa., read a paper on statistical studies of the foramen of Rivinius and of the axis of the external meatus in their relations to intratympanic surgery. He described his method of mensuration of 100 skulls. He found the axis of the bony canal in the vertical plane invariably upward, average 10°, and in the horizontal plane generally forward, average 10°, although one was found of 2° backward. He also presented statistics showing that in only 25 per cent. of 260 drum-heads was the foramen of Rivinius present. It appears to go to prove its developmental rather than its congenital origin. He thought it was rather a large load for Trölsch's white cat to carry.

Dr. Randall also exhibited casts of the calf labyrinth, showing the fact that the ear is fully formed at birth.

Stapedectomy.—Dr. F. L. Jack, of Boston, read a paper on this operation. He recited the indications for operation, and stated that in cases operated on early there is much less resistance and more improvement, and quoted a case where two years after the removal of the stapes the hearing was almost normal.

Dr. Jack also reported eleven operative cases where the lateral sinus was opened or exposed and other complications, concluding with the removal of an osteoma from the meatus, and exhibited the specimen.

Dr. Blake had found the consensus of opinion in regard to the removal of the stapes the same as here.

Dr. Gorham Bacon exhibited photographs of the temporal bone and mastoid cells, also of the membrana tympani.

Thrombosis of the Lateral Sinus.—Dr. C. J. Blake, of Boston, on behalf of Dr. Crockett, of the Massachusetts Charitable Eye and Ear Infirmary, reported a case of lateral sinus thrombosis, with operation and recovery. Recovery was uneventful. Patient took five to seven pints of milk daily and plenty of stimulants.

Dr. Dench thought there may have been too much fear of interference with the sinus.

Dr J. L. Adams, of New York, related a case of removal of the malleus and incus with removal of pus.

Dr. Theobald questioned whether it was the removal of the thrombus or the removal of the pus that was the factor in the favorable termination in Dr. Crockett's case.

Dr. Blake thought it was the soft portion of the thrombus.

Statistics on Deafness Wanted.—Dr. Blake introduced Professor Gordon, of the National Deaf Mute College, as the representative of Dr. A. G. Bell, an honorary member of the society, in behalf of the Volta Bureau for the Increase and Distribution of Information in Relation to the Deaf, and solicited papers or statistics of any kind, which the society would store or distribute. He also inquired in relation to instruments for improving the hearing.

Dr. Knapp and others, who had had experience with the vibrophone, found that at first there was an apparent improvement in hearing, yet it soon vanished. He thought the principle wrong, as strong noises were not good for the ear, and referred to boiler-makers' deafness.

Dr. Walter B. Johnson, of Paterson, N. J., exhibited an insufflator, very simple, and which had been in use many years, but had apparently been overlooked.

Dr. Dench exhibited water-color drawings of the membrana tympani in health and disease, executed by Dr. Ward A. Holden, New York.

Russia has a physician to every 6,000 of the population. In the cities the proportion is about 1 to 3,000, while in many of the rural districts there is only one doctor to every 30,000.

Correspondence.

THE OTHER SIDE OF "MUST THE PARSON PAY?"

To the Editor of the Medical Record.

Sir: I beg leave to call attention to the question, Must the Parson Pay? which is discussed in your issues of April 21st and May 19th. I am not very much inclined to controversy, and while there is a shadow of fact in some parts of both articles, there seems to be a broad, deep selfishness in the articles hardly to be expected from the medical profession, notably founded upon science, education, and philanthropy; but in these two articles the latter principle is eminently wanting. In the first place, it should be understood that the average income of the entire ministry of the United States is *less* than five hundred dollars, and I know of no physician, sticking to his professional choice, who does not get more than that. The quotation from the *British Medical Journal* is evidently founded upon the endowed clergy of the Episcopal Church, a condition not found prevalent in this country. Of course the articles are both intended to shame, instead of dignify, the ministry, by the use of the terms "mendicant," "pauper," etc. That a few clergymen get salaries larger than many physicians, I presume there is no doubt; but that the actual average receipts of all the physicians in the United States are three times as much as the average salary of the ministers, I think there is no doubt.

From the meagre salaries of the ministry, there are philanthropic out-goes, unknown to the other professions, in the thousand and one calls of the church, there is no question. And while the physician charges a dollar a call for *his* services, the minister, as pastor, within the borders of his own church and out of it, makes a thousand calls for which he gets not a cent; but in hundreds of cases takes from his meagre stipend to contribute to the needs of the denizens of the cabin and hovel; and even, as I and others have done, pays the physician for going to the homes of poverty, where he would *not* go if we didn't pay. I am glad to admit that such are exceptional cases, and also that I have received warm and cordial favors in my family from physicians not by any means within the borders of my own church, but of the school of my choice without regard to church, so that I am not inclined to believe the two articles represent the coldness of the medical profession as a whole. I have offered to pay my doctors' bills *always*, and in but two instances have they accepted; but the uniform sentiment expressed has been, "Oh, no, I hope I am not mean enough to take pay from a minister, for he has a hard enough time any way." The two exceptions were: in one case, the doctor was a miser, which is an exceptional case; the other was from sectarian bitterness of opposition to the views I advocate, also an exception. As a rule, physicians are not very great payers to churches, although some are both very liberal and very devout, as the study of anatomy, physiology, and physical conditions has a tendency to materialism, not always prominently outspoken. Your correspondent of North Carolina says: "Some of us (Durham doctors) have rebelled," etc. Well, that is nothing new in North Carolina, whether doctors or others; and in his striving to be witty in denominating the M D.s as Israelites and the ministry as Egyptians, it does us marvellous injustice; for instead of being bondmasters, as a whole, the clergy are bondmen, at the bidding of the public. There is great justice in one point of your North Carolina correspondent's letter, and that is his reference to ministers bolstering up the various nostrums called patent medicines. The most of us are ashamed to know that there is too much truth in that.

To close, let me say that when the medical profession pay out as much money in proportion to what they receive as the ministry, and do more for nothing than the pastors of churches, than the advocates of morals, religion, charity, and philanthropy in the ministerial profession, it will be time to call us "mendicants," "paupers," etc.; and hardly until then.

A Minister.

POTASSIC CYANIDE: HOW MUCH IS A FATAL DOSE?

To the Editor of the Medical Record.

Sir: The killing of the vicious elephant with potassic cyanide suggests the question, How much is a fatal dose for a man? I believe that 2 grains may be regarded as about the extent of tolerance. I am reminded of the case of a young lady who took 2 grains and died in twelve minutes; also of a man in whom 4½ grains proved fatal in less than thirty minutes.

The Medical Record of December 5, 1891, contains the report of a case in which 15 grains were believed to have been taken without a fatal result.

Mr. X——, a druggist, was found in his room in an unconscious state, with livid countenance, dilated pupils, stertorous respiration, etc. Physicians were called, who, having no clew as to what he had taken, suggested no antidote, but recognizing the indication for rousing the nerve-centres, administered ammonia, ether, and other stimulants freely, hypodermically and otherwise.

His former medical attendant was wired, but did not arrive till the patient was so far recovered as to be able to give an account of himself. He said he dropped the poison into a glass, threw in a couple of ounces of whiskey, and drank it off. Selecting a piece from his can, he showed it to the doctor as what he thought was about the quantity he put into the glass. This piece was larger than a Lima bean and weighed 19½ grains; hence it was believed he swallowed at least 15 grains. This, too, when his stomach contained little, if any, ingesta. But this is scarcely probable, since the report is so indefinite throughout as to greatly impair its value. It cannot be supposed that the patient in his then half-dazed condition was very exact in his estimate. Then we know that the cyanide is very sparingly or slowly soluble in ordinary whiskey. And if he drank it down immediately, as we are left to infer, much of the poison may have remained in the glass undissolved. We are not informed that an examination was made to see if any residue remained in the glass or had been thrown out upon the floor of his room.

I have quoted at considerable length from the report because the case was a remarkable one if the guessing on the part of the patient and the doctor were even approximately correct. It was a heroic dose to say the least. But such reports, to be of scientific or practical value, should be characterized by precision and exactness of detail.

C. E. Bennett, M.D.

Cortland, N. Y., May 29, 1894

The American Dentist is credited with many wonderful devices, but a London correspondent of the *British Medical Journal* has discovered an especially new and offensive invention. He says: "Some Americans are introducing here the practice of inserting diamonds for vulgar display into the front teeth. It is surely enough that our sense of decency and propriety should be so often shocked by unsightly gold crowns and fillings, without being further offended by this new atrocity. I believe it has only just started here, and this, therefore, is the time to denounce it, and my excuse for troubling you."

Puerperal Eclampsia.—Drs. Rapin and Monnier, of Nantes, claim to have discovered a bacillus in the blood of women suffering from puerperal eclampsia. It is of dumb-bell shape, the central portion staining more deeply by Gram's method than the ends.

Therapeutic Hints.

Furunculosis.—Spray with carbolic solution two per cent.—PIRONDI.

Dysentery.—Milk diet, and one of the following pills every two hours.

Calomel	60	centigrammes
Powder ipecac	40	"
Extract opium	5	"

—MAGET.

Hypodermic Solutions.—

Creosote pure	gram.	1
Aseptic olive oil	"	14
Iodol or iodoform	"	1
Olive oil	"	29
Crystals of phenic acid	"	1
Olive oil or water with a little alcohol	"	49
Neutral hydrochlorate of quinine	"	1
Distilled and boiled water	"	9
Antipyrine	"	1
Distilled water	"	10

—*Journal de Méd.*

Chronic Alcoholism.—Strychnine, $\frac{1}{40}$ grain hypodermically for the first dose. One twentieth grain was injected on the seven subsequent days, and he was then dismissed with one grain of the drug in sixty pills, which were to be taken one a day every alternate week. At the end of fifteen months the patient reported himself completely cured.—JERGOLSKI.

Anæmia.—To meet the digestive defects:

℞ Hæmogallol ..... ℥ ij.
Fel bovis insp. ..... ℈ ij.
Ext. pancreatini ..... ʒ ij.
Strychniæsulph ..... gr. j.
Caffeinæ mur ..... ℥ j.
Ext. colocynth ..... gr. x to xx.
Ext. taraxac ..... ʒ j.

M. et fit pil. XL. Two t.i.d. after meals.

—PORTER.

Snake Bite.—Inject a ten per cent. solution of chromic acid into the subcutaneous tissue around the wound.—KARLINSKI.

Chronic Gonorrhœa.—

℞ Hydrarg. ox. flav. ..... gr. iv.
Lanoline,
Vaseline alba, ... āā ʒ ss.
Ol. olivæ, q. s

Apply to urethra by means of flexible French bougie of suitable size.

—MARCUS.

Piscidia Erythrina (Jamaica dogwood) in twenty drop doses every two or three hours, is preferred to the usual narcotics in dysmenorrhœa by LIÈGEOIS.

Antipyrin mitigates the pains of uterine cancer, dysmenorrhœa, labor pains, aortic aneurism, etc.—MARTIN.

Diabetes.—So long as opium effects a reduction in the amount of sugar we may safely increase the dose. Glycosurics are singularly tolerant. A combination of liquor opii and acetate of morphia in solution is the best preparation.—RALFE.

Syncope.—Inclination of the head downward and backward, transfusion of blood, subcutaneous injection of a solution of common salt, electrization of the phrenic nerve, artificial respiration, when respiration also is affected at the same time as the heart.—BOBROF.

Leucorrhœa, when chronic:

Cupri sulphate	gr.	xv.
Aq.	℥	viij.

Inject.

—GALLOIS.

Diabetic Coma.—Large doses of castor oil.—SCHMITZ.

Osteomalacia—

Phosph.	centig	.05
Ol. morrhuæ	gram.	50.00

Teaspoonful once daily.

—STEINBERG.

Boils.—Apply on compress:

Chloroform	gram.	30
Essence of cloves	"	5–10
Beechwood creasote	"	1–2
Camphorated oil	"	50

—GOURINE.

Constipation in Infants.—Abdominal massage.

Cocillana.—Five to twenty-five minims of the fluid extract given in chronic bronchitis secures expectorant effect without depression, while it increases appetite.—WILCOX.

Chilblains.—

Oxide of zinc	℥	ss.
Glycerine	℥	iss.
Lanolin	℥	j ℈ iij.

To be rubbed in after washing.

—STERN.

Itch.—

Creolin	2.50
Vaseline	50.00

—DE LOLLIS.

Pertussis.—Rectal injections containing two litres of carbon dioxide mixed with a few centigrammes of pyridin, repeated after each access of cough, or at intervals of a few hours. The worst cases yield to treatment in a week.—BERGEON.

Insect Bites.—

Pulv. ipecac,
Alcohol,
Ether, ... āā equal parts.

Apply.

—*El Siglo Medico.*

Infectious Angina.—

Essence of petroleum	gram.	20 00
Sulphuric ether	gram.	5 00
Powdered iodoform	centig.	0.50
Essence of mint	gtt.	xx.

M. S.: Apply.

—DUMONT.

Tic Douloureux.—Agents which act on the vaso-motor system, such as aconitin, nitro-glycerine, etc.—DANA.

Scrofulous Glands.—Anodal diffusion of iodine with aid of negative pole of galvanic battery.—*Virg. Med. Monthly.*

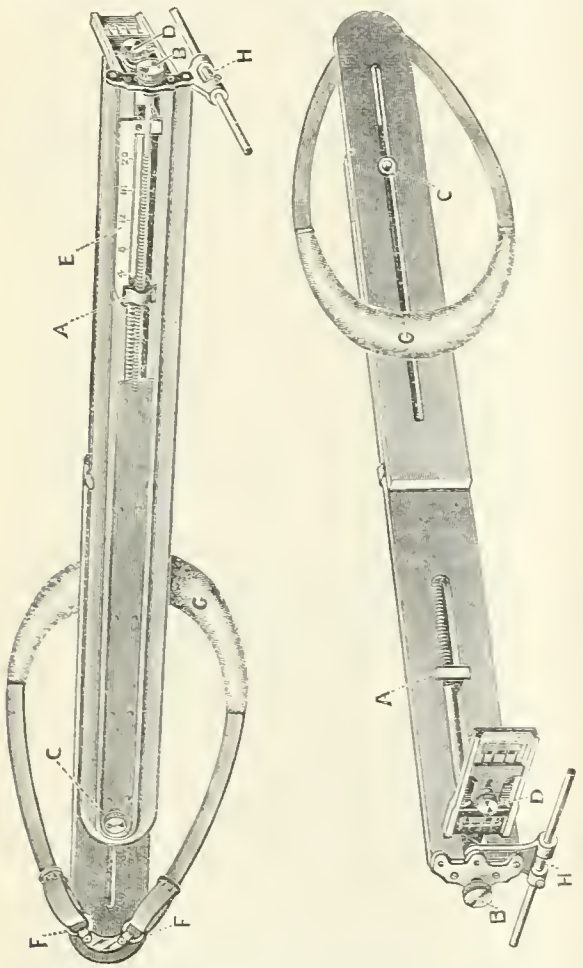
Pneumonia.—Bandage chest in oil-soaked bandages, with dry bandage outside.—PARKER.

In Acute Dysentery, involving the colon high up, enemata containing two or three drachms of subnitrate of bismuth is more efficient than the exhibition of bismuth by the mouth.—WOOD.

Cocaine should be injected into the interior and not under the derm of the mucous membrane or the skin. This is the intradermic method of Reclus, which should be substituted for the hypodermic method. By this means the introduction of a substance into the vein is avoided, and the risk of accidents therefore minimized.—MAGITOT.

Erysipelas Inoculations for the cure of malignant growths is now an established method of treatment. The results in four cases of inoperative sarcoma have been so encouraging that, for the present at least, I have decided to use the toxic products of erysipelas in preference to inoculating the germ itself. The advantages of doing so are very great. The necessity for isolation is avoided and the action of the products can be so carefully regulated that the danger element can be entirely eliminated.—COLEY.

Unpigmented Scars may be improved by tattooing with a skin-colored mixture made with sulphate of baryta, yellow ochre, and water.—PASKIS.



New Instruments.

THE USE OF THE WEED SPLINT FOR EXTENSION OF LOWER EXTREMITY.

By H. A. WEED, M.D.,

LOCKPORT, N. Y.

In presenting the Weed splint for extension of the lower extremity to the profession, I do it after ten years of use in private practice, with the conviction that it will prove a more convenient and efficient means of obtaining continuous extension of the lower extremity than any now in use, and will save the busy practitioner much valuable time and trouble. The splint being attached to the patient only, and not in any way fastened to the bed, makes it far more convenient and easily adjusted than the weight and pulley, for the reason that any smooth, hard bed at hand can be used; while with the weight and pulley a specially arranged bedstead must be obtained, and much valuable time lost in preparing to reduce the fracture. The Weed splint has a spiral spring

so arranged, that it will keep a steady tension on the limb at all times, and of sufficient strength to fulfil all necessary requirements.

The patient may be moved from one bed to another, or his position changed, at any time, without disturbing the dressings, or removing the extension. With the Weed splint there is no tendency of the patient to slide downward in the bed; or should the lower end of splint rest against the foot of bed, it would not affect the extension on the limb in the least. The splint will maintain a steady tension of from one to twenty-five pounds, as the operator may desire.

In reducing a fracture of the femur with the Weed splint where there is much shortening, the tension being applied with a fine screw, the limb will be brought down so gradually that the reduction will be accomplished without pain.

The Weed splint has a long lateral wood support, extending from the bottom of the foot to the armpit, thus giving ample support to the injured limb, and keeping it at all times in line with the body; and in case of hip or knee joint disease, where extension is indicated, keeping the joint as nearly as possible motionless.

The Weed splint also supplies a valuable addition to the appliances for ambulance use. The long lateral wood splint affords facilities for binding and supporting the broken limb, while the ready application of extension at the place of accident prevents the ends of the broken bone from seriously injuring and lacerating the soft parts, and the severe pain caused thereby, while in transit to hospital.

Medical Items.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 2, 1894.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	5	1
Scarlet fever	114	12
Cerebro-spinal meningitis	1	8
Measles	152	6
Diphtheria	213	68
Small-pox	44 [1]	6
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

[1] Eight of this number were received at hospital preceding week for observation.

Suppression of Italian Universities.—The Government of Italy has decided to close the universities of Catania, Messina, Modena, Parma, Sienna, and Sassari, in each of which there is an average attendance of only a little over one hundred students. The revenues of these universities will be apportioned to the others in the kingdom, of which there still remain far too many.

The Russian Government promises an appropriation of 50,000 rubles to help defray the expenses of the next congress to be held in that country.

Dr. Haffkine is at present in India engaged in his propaganda of anti-cholera inoculation. He has been seconded in his efforts by the members of the Indian Medical Service and the native physicians. The credit of the idea, whatever the ultimate value of the procedure may be, belongs without doubt to Ferrán, of Spain.

Dr. J. W. Ballantyne, of Edinburgh, has brought out the first number of *Teratologia*, or "quarterly contributions to antenatal pathology." This is entirely a new step in medical literature. The contents of the first number consists of a long and interesting paper on the fœtus amorphous, embellished with three plates. Then follows an article on "Fœtal Pathology in the Past," and the concluding papers are taken up with reviews, abstracts from current literature, etc.

"Quacks."—The Lady Morgan of my early days (writes Autolycus, in the *Pall Mall Gazette*) used to quote the following (supposed) correspondence with the late Dr. Jenner:

> I've despatched, dear Lady Morgan, this scrap of a letter
> To say that Miss Charlotte is certainly better.
> A regular doctor no longer she lacks,
> And therefore I've sent her a couple of quacks.
> (With the above note came a couple of wild ducks.)

Lady Morgan's reply:

> Yes, 'twas politic truly, my very good friend,
> Thus a couple of quacks your patient to send,
> Since there's nothing so likely as quacks, it is plain,
> To make work for a regular doctor again.

TWO CASES OF INTRA-CRANIAL NEURECTOMY.[1]

BY GEORGE R. FOWLER, M.D.,

BROOKLYN, N. Y.

CASE I.—M. C——, female, aged forty-five, was transferred to my service at St. Mary's Hospital, from the Neurological Department under Dr. Newton, for surgical treatment directed to the relief of an intractable left-sided trigeminal neuralgia of nine years' standing. Every measure of treatment, both rational and irrational, had been tried in vain, and at last she was glad to avail herself of the advice of Dr. Newton, who urged her to submit to operative interference.

The patient was a rather florid and robust-looking Irishwoman, who did not present the appearance of one who had suffered greatly and for so long a period. She had not acquired any narcotic habituism. Hyperalgesia was excessive and almost constant. During the past three months the frequency and intensity of the paroxysms had increased to a marked extent, so that the patient declared that she could not be considered responsible for any act, even to that of self destruction.

FIG. 1.

The parts principally affected by the pain are shown in Fig. 1.

Operation, August 10, 1893; anæsthetic, chloroform.—An omega-shaped incision, after the manner employed in the Krause-Hartley operation, was made, its posterior leg lying in front of the tragus and its anterior at the external angular process of the frontal bone. In carrying the first-named to the proper depth the trunk of the temporal artery was split, which gave rise to a sharp hemorrhage. In order to secure the bleeding points, it became necessary to detach the soft parts from the bone to some extent. Considerable blood was lost at this stage of the operation. The wider of the gouge chisels of Hartley was then employed to cut a groove in the bone of the same shape and extent as the omega-shaped incision in the soft parts. The groove was first cut to a depth equal to the antero-posterior thickness of the gouge, after which it became wedged and was laid aside for the narrower one of the set. This first cut just entered the diploë, from which the hemorrhage was most profuse, in some parts of the groove escaping in a per saltum stream. All attempts to check this were futile, and it soon became apparent that nothing short of completing the bone section and lifting up the bony flap would permit access to the source of the bleeding. The groove was then rapidly deepened. The extreme thickness of the bone rendered this portion of the operation extremely difficult, and all the time a most profuse hemorrhage was going on. The gouge became wedged rapidly, and it became necessary to complete the section with the corner of the flat, narrow chisel of Hartley's set. The bony flap was finally pried loose, breaking in three pieces. After turning down the flap the bleeding from the diploë ceased. The opening was enlarged by means of Keen's model of the Luer punching forceps. The middle meningeal artery passed through a canal in the bone, and was necessarily torn by the downward displacement of the flap. The vessel was secured at the point of rupture, and the dura carefully separated from the base in the anterior fossa. The frontal lobe was held in an upward direction by Dr. Bristow, my assistant. In approaching the foramen ovale care was taken to keep well in front of the groove in which the middle meningeal artery runs, in order to avoid tearing this vessel at the foramen spinosum. In fact, so far did I separate the dura anteriorly at the cavum Meckelii that the foramen ovale was passed, and the foramen rotundum, with the second division of the trigeminus, reached first. Yet, in spite of this precaution, and the valuable aid furnished by an electric lamp and condenser, whereby the entire field of operation was perfectly lighted up, the middle meningeal artery was torn at the foramen spinosum, and a free hemorrhage took place from this point. This was temporarily checked by the finger, and finally permanently arrested by an aseptic plug driven into the foramen. The second division of the fifth was now divided at the round foramen, and the oval foramen and the third division sought for. This was found lying just to the inner side of the foramen spinosum, instead of the latter being placed a quarter of an inch or more posteriorly to the level of the foramen ovale. With this arrangement of the foramen, it would have been a physical impossibility to have isolated the third division of the trigeminus at the foramen ovale without loosening the dura where the middle meningeal artery leaves the foramen spinosum. Both nerves having been divided, about an eighth of an inch of the second division was resected. Following the section of the third division quite a copious venous flow occurred, and as the patient's condition was most unpromising, further efforts were abandoned and the wound closed.

The time occupied in gaining access to the skull and identifying the two divisions of the nerve was just one hour. The further steps of the operation, including the suturing of the soft parts and placing the dressings in position were completed in twenty-five minutes. The length of time in which the frontal lobe was lifted and compressed was fifteen minutes. During this time the patient gave evidences of compression by stertorous breathing, and finally showed the effects of the displace-

[1] Read before the Brooklyn Surgical Society, March 15, 1894.

ment of the cerebro-spinal fluid from the lateral to the third and fourth ventricles, and thence to the respiratory tract, by the occurrence of progressively diminishing respiratory efforts.

The patient was infused with saline solution by my assistant, Dr. Walter Wood, while I was completing the operation proper. After leaving the operating-table the pulse fell in the course of four hours from 140 to 80. Suddenly, and without warning, however, the respirations fell to below 20; in five minutes they fell to 10, and in five minutes more they ceased altogether. The pulse continued at the wrist for half a minute or more after the respirations ceased. Attempts at artificial respiration were of no avail.

Case II.—M. P——, male, aged forty two, was admitted to my service at the Methodist Episcopal Hospital, suffering from an intractable left-sided facial neuralgia referred to the distribution of the second and third divisions of the fifth nerve. The history of the case extended over a period of thirteen years. During the first year of his sufferings he had consulted me with a view of obtaining surgical relief, but an interview which he subsequently had with one of my patients, upon whom I had operated for trigeminal neuralgia by the method of perforating the anterior and posterior walls of the antrum of Highmore, and removing the second division of the fifth nerve, together with the Meckel's ganglion from the spheno maxillary fossa, resulted in his declining to accept my

Fig. 2.

advice at that time. The reasons assigned for this declination related to the disfigurement involved, and the paralysis of sensation in the area of distribution in the superior maxillary division of the fifth in the case alluded to.

During the intervening twelve years he had suffered almost constantly. An exostosis of the left inferior turbinated bone had been accused by a nose specialist as a cause of the neuralgia. This was removed, but no relief followed. Some of the peripheral branches had been divided with the same result. The patient then attempted to obtain relief by the use of large doses of morphine, but when three grains, administered every hour or two failed to give even temporary relief, he was placed under my care by his family physician, Dr. Fuchs. The area of pain is shown in Fig. 2.

Operation, February 10, 1894; anæsthetic, chloroform.—The external carotid artery was ligated preliminary, at a point just above the facial and occipital, with the view of shutting off the blood-supply to the internal maxillary and its middle meningeal branch. The cavity of the cranium was then opened by the Krause-Hartley method and the third and second divisions of the fifth isolated in turn. About three sixteenths of an inch of the second division was resected; less than this amount of the third was removed. The Gasserian ganglion was so intimately adherent to the dura that it was found impossible to isolate this.

The only bleeding of any account was from small venous branches as the dura was lifted up from the base; and from the two or three small veins which accompany the divisions of the nerves as they pass through their respective foramina. Time from the establishment of narcosis till the removal of the patient from the operating-table, one hour and five minutes. Time from the opening of the cranium to the final replacement of the frontal lobe in position, eight minutes. Most of the latter time was occupied in placing folds of gauze between the frontal lobe and the base and waiting for the oozing, which somewhat embarrassed this stage of the operation, to cease. No violent hemorrhage took place at any time during the entire operative procedure. The middle meningeal artery furnished almost no blood whatever, although it was injured in turning down the flap and separation of the dura from the base. No attempt was made to prevent this.

The patient rallied well from the operation and made a speedy recovery. No further morphia, beyond a sixth of a grain during the first night, was administered, nor was any more necessary. There was no craving for the drug. Union by first intention was secured in both wounds, the patient sat up in seven days and walked about in ten days from the operation. He was discharged cured at the end of fourteen days.

The area of complete anæsthesia following the operation coincided pretty accurately with pre-existing hyperalgesia, while the area of lessened sensation corresponded to some extent to the region to which the radiating pains extended before the operation.

The following are some of the points of interest in connection with these cases:

1. The difficulties in the way of gaining rapid access to the skull. This was particularly noticeable in the case of the woman. A portion of the bony flap was so detached in the effort to secure the bleeding points in the posterior leg of the omega-shaped incision as to require its removal altogether. It was through this portion of the bone that the middle meningeal artery passed, and, as will be seen, in addition to this and the fact that the bone was unusually thick, the vessel itself was larger than is generally encountered in this locality. Professor Keen, of Philadelphia, has recently attempted to substitute the surgical engine and burrs or drills in order to facilitate this step of the operation. The employment of the common trephine and subsequent enlargement of the opening by means of the punching forceps of Luer would probably greatly facilitate this stage of the operative procedure. The disadvantage which it involves of not being able to replace the bone with the flap is probably of less importance than the time consumed in the method of Hartley. In one of Krause's cases this surgeon chiselled away a sufficient portion of the thinnest part of the temporal bone to admit the points of the Luer's forceps, following which, with the latter instrument, the original opening was rapidly enlarged in the required direction and extent. By the aid of a dull raspatory and the ends of the fingers, the trunk of the middle meningeal and the second and third divisions of the fifth were made visible, leading to the ganglion. Krause[1] decided, from his experience in this case, that no harm can arise from not returning the bone. This also agrees with general experience in trephining for traumatism, in which class of cases we not infrequently remove portions of bone much larger in size than the bone flap turned down in Hartley's method. The crunching effect of the Luer forceps is very serviceable in arresting hemorrhage from the diploë. I have not infrequently availed myself of this use of the forceps, applying it to the margins of a trephine opening, not so much for the purpose of enlarging the latter as to force

[1] Deutsche Med. Wochenschrift, No. 15, 1893.

the outer table of the skull upon the diploë and thereby arrest the bleeding from the latter.

In a future case I should turn down a flap of the soft parts, temporarily resecting the zygoma, if necessary; trephine upon as low a plane as possible, enlarge this opening by means of the Luer forceps, and thus enter the cranial cavity at a point in as close proximity to the location of the Gasserian ganglion as possible.

2. The excessive hemorrhage prior to gaining entrance to the cavity of the cranium was a marked feature of the first case. This was due, first, to the fact that the posterior leg of the omega-shaped incision, in its passage in a downward direction in front of the tragus, split the large temporal terminal of the external carotid artery. A most vicious spurt of blood took place at this, which, although temporarily held in check by pressure below the lower extremity of the incision, necessitated the detachment of the soft parts, and consequent delay before it could be brought under permanent control. In the second place, another source of dangerous hemorrhage at this stage was found when the diploë was entered during the chiselling away of the bone to form the groove upon the line of the incision in the soft parts. The vessel proved to be fully as large as the radial. The bone at this point was considerably thicker than the average normal (fully a quarter of an inch), which fact, together with the size of the artery, and the inability of the latter to retract readily within the bony canal through which it passed, was the occasion of vexatious and even dangerous delay, to say nothing of the larger amount of blood lost. These disadvantages were perfectly met in the second case by the preliminary ligature of the external carotid artery. The ligature was placed above the facial and occipital branches, thus cutting off the supply from the trunk of the internal maxillary with its middle meningeal branch, and the temporal terminal of the external carotid. This point was selected because of the free anastomosis of the lingual, facial, and occipital branches with those of the opposite side, and through the medium of which the circulation is restored to all of the ramifications of the external carotid when the ligature is placed below these branches. Not only was the hemorrhage greatly lessened by this procedure, but the further steps were greatly facilitated. No fear of bleeding resulting from tearing the middle meningeal at the foramen spinosum was entertained, and detachment of the dura from the base was proceeded with with comparative rapidity and satisfaction.

3. Prolonged pressure exerted upon the cerebrum in the retraction of the frontal lobe was most assuredly the occasion of driving the cerebro-spinal fluid from the lateral ventricles to the medulla and respiratory tract, in the first case. As a result of experience gained in this case I have concluded that the pressure must be as slight as possible consistent with getting a view of the parts, and that it should always be in a direction to lift the brain from the floor of the skull, just as it is lifted in autopsies by the post-mortemist as he reaches beneath the brain with his fingers before dividing the nerves at the base. With a good electric lamp and condenser sufficient light may be thrown into an opening which may be safely obtained, to identify and trace the meningeal to the foramen spinosum, in doing which the operator is led directly to the ganglion. Preliminary ligation of the external carotid does away with necessity of division of the middle meningeal between the ligations when this is obstructive, as it proved to be in the first case. As the brain is lifted in an upward direction the nerves are brought into view, and the limits of their foramina distinctly outlined. There can be no question that the brain will bear a much greater amount of pressure than is generally supposed, and that the evil effects of pressure arise, not so much from direct actual force applied to the structure of the cortex as to the resultant displacement of the cerebro spinal fluid.

4. Unless the bone chance to break at the very lowest point possible, rupture of the middle meningeal artery is almost certain to occur as the bony flap is turned down, particularly in the cases in which the vessel passes through a bony canal instead of lying in a groove. With preliminary ligation of the external carotid artery, as practised in the second case, this rupture is of but minor importance. Without preliminary ligation the plan of entering the cranium low down, with perhaps osteo-plastic resection of the zygoma, and removing the bone at once instead of attempting to utilize it for the purpose of closing the opening, will avoid rupture of the vessel in so far as it is possible to do so, for the reason that the artery is reached relatively nearer to the foramen spinosum than in the Hartley method.

5. The free venous oozing which took place in connection with lifting the dura mater from the base, as well as when section was made of the second and third divisions of the fifth, is worthy of notice. Even in the second case this was marked, and appeared to come from small venous radicles upon the dura, in the first place, and secondly, from the divided ends of the small veins emptying into the temporal, sometimes two or three in number, which pass, together with the third division of the trigeminus, through the foramen ovale, in addition to the emissary veins, which are sometimes of considerable size and connect the cavernous sinus with the pterygoid and pharyngeal plexuses.

6. The Gasserian ganglion was not removed in either of these cases. In the first case the patient's condition did not admit of further interference after the second and third divisions of the fifth had been divided. In the second case an attempt was made to peel back the dura in order to remove or break up the ganglion. The membrane was found to be so adherent that it was not deemed safe to exert the requisite force for fear of injuring the immediately adjacent and intimately connected cavernous sinuses.

7. The amount of nerve-tissue removed did not exceed $\frac{3}{16}$ of an inch. The extent to which the nerves may be removed must necessarily vary in different cases. Doyen, of Reims, presented, at the last congress of French surgeons,[1] the Gasserian ganglion with its three branches entire, taken from a patient, whom he likewise presented. The portions of the ophthalmic and superior maxillary divisions each measured 15 mm. ($\frac{3}{5}$ of an inch); the portion of the inferior maxillary or third division is stated in the report to have measured 40 mm. ($1\frac{3}{5}$ inch). In one of Krause's cases the entire width of the ganglion was grasped by means of Thiersch's avulsion forceps, after dividing the branches as far down in the foramina as possible, and both ganglion and 20 mm. ($\frac{4}{5}$ of an inch) of the nerve-trunks were turned out and removed.

8. The course of the healing was exceedingly rapid, and this has been a feature of the cases heretofore reported. In one of Krause's cases the patient left his bed on the seventh day.

9. It is to be noted that the area of anæsthesia in the successful case herewith reported is somewhat smaller than the pre-existing area of hyperalgesia, while the area of impaired sensation corresponds rather accurately with the region to which the pains radiated before the operation.

Michael Servetus.—The medical students of the University of Madrid are organizing a memorial function in honor of Michael Servetus, on the occasion of the three hundred and forty-first anniversary of his death, which falls on October 27th. The celebrated philosopher and anatomist, for whom the honor of having discovered the circulation of the blood has been claimed on somewhat insufficient grounds, was born at Saragossa in 1509, and burnt as a heretic at Geneva by Calvin in 1553. Señor Castelar and Professors Letamendi and Calleja, of the Medical Faculty of the University of Madrid, are expected to be among the speakers at the proposed memorial festival.

STACKE'S RADICAL OPERATION FOR OBSTINATE CHRONIC OTORRHŒA.[1]

By WALTHER VULPIUS, M.D.,

NEW YORK.

ASSISTANT SURGEON TO THE NEW YORK OPHTHALMIC AND AURAL INSTITUTE, AND INSTRUCTOR IN OTOLOGY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

AMERICAN otologists were among the first who fought for the re establishment of the mastoid operation, which had been a forlorn post since the fatal issue of the case of von Berger in the year 1791. This man had died a victim to a wrong indication and the deficient knowledge of the average anatomical structure of the involved parts, as well as of the manifold possibilities of individual deviation in size and shape from this average. For half a century afterward otologists and surgeons were unanimous in condemning the operation, and it required a strong scientific conviction and courage to advocate its more extended execution on the ground of the few scattered—and most of them timidly made—experiences up to the year 1868.

At that time Dr. Jacoby, in Breslau, collected fourteen recorded cases, and added one out of his own practice, in which he had opened the mastoid cells by means of a drill. He divided them into two categories, and gave four different indications for the operation.

In most of these fifteen cases an acute middle-ear suppuration had led to the mastoid complication which became manifest by an abscess behind the auricle and carious destruction of the bone.

But von Troeltsch already, who in the year 1858 had perforated the mastoid cortex after a Wilde's incision by a trembling movement with a probe, suggested in the report given of this case in *Virchow's Archiv* (1861) that the opening of the mastoid process could eventually be considered as a means for healing obstinate chronic middle-ear suppurations. Following this, and another private suggestion from Professor Schwartze's side Jacoby gives as his fourth indication a condition in which chronic middle ear suppuration refuses to yield to other methods of treatment. A similar indication, with the restriction of frequent and painful exacerbations was laid down by Dr. Roosa, of this city, in a paper published in the MEDICAL RECORD, July, 1870.

But it seemed still too dangerous to chisel or bore down through a sound-looking cortex into any depth of the mastoid process without the guide of a fistula or carious defect, or the pressure of threatening symptoms, particularly as even the scarce experiences made hitherto had revealed great individual varieties in the anatomical structure.

Therefore the fourth indication of Jacoby could hardly induce any operator to put it to a practical trial until the excellent studies of Schwartze and Eysell on the anatomy, physiology, and pathology of the mastoid portion of the middle ear were published in the *Archiv für Ohrenheilkunde*, 1873, followed by the report of sixty-three pertaining cases, seventeen of which were operated on by Schwartze himself. Further contribution to the anatomical studies were made by Bezold in the *Monatschrift für Ohrenheilkunde* from November, 1873, to March, 1874. In the following year Schwartze began the publication of his first series of fifty of his own operations, which was followed by a second one concluding in 1883.

Among these hundred cases a number of uncomplicated chronic ones of otorrhœa had been operated on according to the fourth indication of Jacoby; but in his "Lehrbuch der Chirurgischen Krankheiten des Ohres" (1885) Schwartze declares this number to be too small to entitle him to a final decision of the question whether the mastoid operation could be recommended as a means of healing obstinate chronic middle-ear suppurations without apparent mastoid complications. But nevertheless he repeats this indication as his fifth, in the same text-book, and continually fostered the hope that it would in time become more and more justified by a further development of the operating method.

Up to that time the final results of the operation in cases of uncomplicated chronic middle-ear suppuration were so rarely satisfactory, and the after-treatment so long, extremely tiresome for the physician, and painful for the patient, that only in a few places outside of Halle, the residence of Professor Schwartze, was it taken up as a regular method in practice. One pupil of Schwartze, the late Dr. Ferrer, in San Francisco, endeavored to establish the prophylactic mastoid operation—as Schwartze called it—in this country, but does not seem to have found many sympathizers. On the contrary, symptoms of indifference toward this question could be perceived, and from one side, in Dr. Sexton's book, "The Ear and its Diseases" (1888), an utter and uncritical reaction against any kind of mastoid operation was preached. The intense interest and exertions of the American profession had shifted to other surgical procedures, which had been introduced in otological therapeutics, above all to the excision of the ossicles, with the purpose of either healing chronic middle ear suppurations or improving the hearing and tinnitus. When I tried to find out the reason for this predilection, I thought to find the clew in a statistical relation, viz., that the most treacherous of chronic middle-ear diseases, the cholesteatoma, seems to be much less frequent and serious here than it is in Germany and Austria, while here the sclerotic processes, or dry middle-ear catarrhs, prevail considerably, both in frequency and gravity.

I need not enter here on criticising the results of the ossiculectomy made for the relief of deafness; but I have to state that the same operation, if executed for the healing of chronic middle-ear suppurations did here as little as in Germany fulfil all the hopes which had been set on it. For there is a number of cases where the operation cannot be done sparingly and successfully on account of the narrowness or tortuousness of the auditory canal, and a much greater number in which the caries is not limited to the ossicles, but involves the adjacent parts of the middle ear, will further maintain the suppuration and require more radical methods of treatment. While thus the otologists were at work to attack chronic middle-ear suppurations by improving their methods of, and extending and clearing their indications for, mastoid operations on one side, and intratympanic ones on the other, a fresh impulse was given by two German surgeons, Küster and von Bergmann, who broadly applied general principles of the treatment of chronic suppurations within rigid walled cavities to the middle ear, without paying much respect to the sensory function of this organ and the inviolability of the facial nerve. But nevertheless these suggestions of more radical methods of operation were not lost on the otologists, and the same Dr. Stacke, who in the *Berliner Klinische Wochenschrift* (No. 16, 1889) refuted the unjustifiable charges of Professor von Bergmann against our specialty as practising obsolete and unsurgical methods, afterward elaborated an operative method which is as sparing as the otologists and as radical as the surgeons could ever demand.

The first communication of this method was made to the International Medical Congress at Berlin (1890), as an appendix to Stacke's paper on the indications for ossiculectomy. The main principles of it had also been advocated and partly practised by Hartmann, Zaufal, Arbuthnot Lane, and others, but when, in the following year, at the "Deutsche Naturforscher- und Aerzte-Versammlung," in Halle, Stacke described his new and original method of skin-transplantation, whereby it became possible to secure a condition which allowed forever a perfectly free inspection of all the middle-ear cavities, and left no complication of these cavities behind, the superiority of his method became so evident that it was adopted by the most eminent otologists in Germany, and certainly deserves further propagation. It was introduced into the Ear Clinic at Halle, and benefited for its further development from the eminent ex-

[1] Paper read before the Ophthalmological and Otological Section of the New York Academy of Medicine, January 15, 1894, with demonstration of two cases.

perience and sound criticism of Professor Schwartze; two series of fifty cases each have been published from this clinic in the *Archiv für Ohrenheilkunde*, and valuable suggestions have been given for modifications in certain cases.

The Stacke operation is indicated as the final and most radical means of treatment in cases of chronic middle-ear suppuration, which is maintained either by cholesteatoma of the attic and antrum or by caries, if the latter cannot be with certainty confined to the ossicles. I say as a last resort, for I do not think so severe a procedure justifiable before more sparing methods have been thoroughly tried and proved to fail. Only if threatening complications or abscesses over the mastoid region immediately require an opening of the antrum, it is, in most chronic cases of middle-ear suppuration, advisable to make at once the more radical Stacke operation, which shortens the time of after-treatment and gives better chances for a permanent cure of the otorrhœa.

I need hardly say that the operation should never be made in cases of mastoiditis complicating an acute otitis media purulenta.

A description of the technique has been given several times in the American medical literature. One in the recently published hand-book, of Burnett, on the diseases of the ear, nose, and throat, is very short, and corresponds to the first report given by Stacke in Berlin. That of Dr. Allen in his nice little book, "The Mastoid Operation," is largely influenced by transitory views that were held for awhile in Professor Schwartze's clinic at the time when Dr. Allen attended it. He advocates in it a radicalism, which has been given up in Halle on account of its dangers for the facial nerve, and against which Professor Schwartze, in his new hand-book on ear diseases warns most expressly, the same as Stacke had done in his second report. The minute description of Dr. Holmes, in the twenty-second volume of the *Archives of Otology*, represents the most advanced stage of the method as it is now practised in Halle, but only slightly differs in its result from the original Stacke operation.

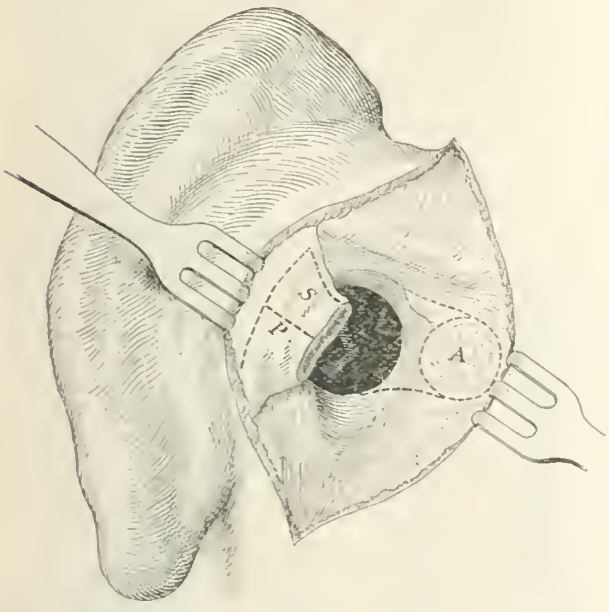

FIG. 1.—Shows the detachment of the auricle and shelling out of the membranous meatus. The dotted lines on the latter mark the cuts by which one (S=Stacke) or two (P=Panse) transplantation-flaps are formed. The vertical cut is the same for both. The dotted lines behind the meatus circumscribe (*a* the region for the typical mastoid operation and for the resection of the posterior wall of the meatus.

With the aid of some illustrations—the same which I drew for Dr. Stacke's lecture in Halle—I can be rather short with my own description of the technique: A long, slightly S-shaped incision circumscribes and detaches the auricle from its insertion ending on the tip of the mastoid process. By pushing back the periosteum, the surface of the mastoid is laid bare behind the meatus, and in the latter its cutaneous coating is loosened, transversely cut as near to the tympanic ring as possible, and entirely drawn out with a blunt hook. Originally the further procedures of Stacke were to pass his curved "protector" into the attic and to chisel off with a bent gouge that part of the upper wall of the osseous canal which prevents a free inspection of the attic and the tegmen tympani from the outer meatus. The carious ossicles —or what is left of them—were then removed, and a curved probe passed backward through the aditus or neck

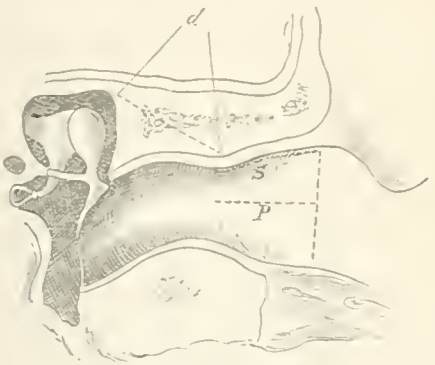

FIG. 2.—Posterior Half of a Frontal Section through the Auditory Canal and Drum Cavity of a Left Ear. Dotted line *d* shows what has to be chiselled off to make the attic and tegmen tympani accessible from the outer meatus; *S* and *P* signify the same as in Fig. 1.

of the antrum, to make out, if possible, whether this cavity is diseased; and if so found, to serve as a guide for chiselling it open through the posterior wall of the osseous canal (Fig. 1). Experience has shown that concurrent disease of the mucous membrane or the osseous walls of the antrum is present in by far the most cases of chronic otorrhœa, and can hardly ever be excluded with absolute certainty. It has therefore been found more convenient first to open the antrum after the typical method, to pass a probe forward into the drum-cavity, and to remove the big wedge shaped piece of bone, which forms with its anterior side the posterior wall of the meatus, laterally the border between the meatus and the wide mouth of the funnel-shaped operative cavity, and with its narrow medial portion the lateral wall of the aditus ad antrum. The removal of this last piece has to be done very cautiously, because right across, forming the slightly protruding "threshold" on the medial wall of the aditus, the facial and the horizontal semicircular canals are situated. Dr. Allen gives the dangerous advice to cut down the ridge, which now is left medially between the drum cavity and the antrum, and thus to make the lower wall of the meatus in its whole extent pass uninterruptedly into the lower wall or floor of the antrum. But there

FIG. 3.—Drum Cavity with Stapes *st* in Relation to the Operative Cavity. *t*, tympanic cavity; *a a*, aditus ad antrum; *a*, antrum; *t.p.*, rest of posterior wall of meatus.

are, as Schwartze points out, varieties in the course of the descending part of the facial nerve, which make it dangerous to use the gouge too liberally beneath the adit (Figs. 2 and 3).

There is much more room now for the opening of the attic and the extraction of the ossicles, and we need not, if the meatus is wide enough, shell out the whole cutaneous coating, but will find it sufficient to detach it only

along the posterior wall and press it with a slender blunt hook against the anterior one. This is a great advantage for the after-treatment; for if the cutaneous coating remains partly fixed to the tympanic ring, it cannot recede and leave the osseous canal uncovered to a great extent, and thus necessitate the slow formation of great streaks of new lining. This valuable suggestion has been given by Dr. Panse in the *Archiv für Ohrenheilkunde*, vol. 34. We finally split the posterior wall of the membranous meatus horizontally up to the concha, cross this section by a vertical one, and form that way one (Stacke) or two rectangular flaps (Panse), which are thrown back and fixed upon the walls of the operative cavity by tampons or loose sutures passed to the posterior edge of the first post-auricular incision.

The after-treatment has the object to bring about the lining of the big, uncomplicated cavity, which comprises the former drum cavity, attic, aditus ad antrum, the antrum itself, and the defect of the posterior wall of the osseous meatus, with a dry and smooth epidermoid membrane. The last-described transplantation serves this purpose excellently, but it can be still more promoted by the implantation of small pieces of fine skin from any remote part of the body, as Dr. Siebermann suggested in his paper on the operative treatment of cholesteatoma in the *Berliner Klinische Wochenschrift*, No. 1, 1893. The struggle with exuberant granulations, which has to begin in the second or third week, by tamponade, cauterization, especially galvano-cautery, or excision, is sometimes very hard and tiresome, for there are cases in which everyone of the just-mentioned measures seems to act as a stimulant for the augmented production of new granulations, checking and suppressing the progress of epidermization. In such cases it is advisable from the sixth or eighth week to leave off the tamponade or other irritating applications for awhile, which will sometimes induce a rapid extension of the epidermoid layer. One of the cases which I am going to demonstrate to you was of this character, and Dr. Gruber makes the same remark in his last paper on the Stacke operation in the *Archiv für Ohrenheilkunde*, vol. 35. Except one or two sutures, which close the upper angle of the wound, the post-auricular opening ought to be kept open for three or four weeks till all relations have become quite distinct and the epidermization is fairly started.

The hearing is hardly touched to any extent by the operation; it is sometimes improved; and I do not know a case in which a serious deterioration has been caused by it.

Of the two cases which I have brought before you one came under my treatment the day when I entered the New York Ophthalmic and Aural Institute, October, 1892. The girl, at that time twelve years of age, had been suffering from a double-sided chronic otorrhœa ever since she had had the scarlet fever in her third year. Almost from the beginning the ear-trouble had been judiciously tended, but without any considerable or lasting success. The hearing in the left ear was practically nil; while with the right one ordinary conversation could be understood in close proximity. There were no pains in the left, but frequent spells of aches and great tenderness against syringing or any other manipulation in the right ear. On both sides the auditory canals were plugged with polypi. These could thoroughly be removed after cocain instillation from the left ear, but required ether-narcosis for the right one. In spite of alcohol instillation and other medications the polypi would obstinately grow up again, and I had to repeat the operation several times in the course of five months. In both ears the drum-membranes were entirely gone and nothing of the ossicles visible; caries was felt if a curved probe was passed into the attic—even this being a very painful procedure in the right ear. The growth of granulations stopped in the left ear in April of last year, and there was no more discharge from the beginning of May. But the condition of the right ear was unchanged, and I was afraid lest the hearing might still further be reduced. I proceeded therefore to make the Stacke operation on May 6th. I opened the attic first and removed from it besides granulations small remnants of the malleus and incus, including the joint. A probe passed into the antrum brought out caseous matter, which caused me to open this cavity after the original Stacke method. The antrum was very small, its communication (or aditus) with the drum extremely narrow, and the outer cortex very thick and sclerotic. On account of the narrow aditus the above-mentioned ridge was left comparatively high and projecting. After a fortnight, which afterward proved to be a little prematurely, I closed the outer wound by secondary suture, but from the fourth week an enormous production of granulations from every side set in, menacing to grow together and thus forming bands and incontrollable recesses. Every conceivable caustic, and the most careful daily tamponade were applied without good effect, and the propagation of epidermis stopped entirely. Therefore I changed the treatment, from August 10th, into a simple cleansing once a day, and was very much pleased to see the epidermis spread out rapidly and cover the whole cavity within two weeks. In one place only, across the groove which leads medialwards into the antrum (*i.e.*, the defect of the posterior wall), a small transverse attachment of granulations had formed, which after complete epidermization grew so thin and unobstructive that I could leave it undivided for demonstration's sake. From the end of August the ear has remained dry; no pains have recurrred and the hearing is somewhat improved, so that the girl, who formerly had to be seated quite near her teacher, is now able to understand him at a distance.

The second case presented itself on July 10th, last year, with the history of a running right ear since two years or so, frequent headache, and periodical attacks of deep-seated pains in the mastoid region. The meatus was narrow and tortuous, the anterior part of the drum-membrane and the hammer looked healthy as far as visible; a granulation of moderate size covered the posterior and upper part. After its removal a cicatrized semicircular defect of the lateral osseous wall of the attic above the short process of the hammer, and a big, dry perforation in the posterior half of the drum-membrane became visible. The granulations had grown from a fistulous opening, which could not be seen, but felt with a curved probe, leading from the inferior posterior nook of the drum-cavity in a backward direction. At the same time the probe gave evidence of a carious condition. After repeated unsuccessful trials to arrest the growth of fresh granulations, and the painful symptoms of obstruction caused thereby periodically, I proposed the radical operation, and performed it on December 7th. This time I first opened the antrum, this cavity undoubtedly being the principal seat of the suppuration. The cortex was of marble-like hardness and nearly one inch and a half thick. The antrum, of about normal size, contained some creamy pus. I tried in vain to pass a probe from there into the attic and was therefore obliged, in chiselling off the medial part of the posterior wall of the meatus, to follow the probe, which was passed from the drum-cavity into the fistula. When I finally laid open the attic, the posterior part of it was seen to be plugged by an osteophyte, which extended from the short process of the anvil along its entire length to the tegmen tympani, and in that way obstructed entirely the aditus ad antrum. I carefully detached this piece from the tegmen, and it came out in connection with the anvil. This explains why the pus produced in the diseased antrum was obliged to seek another outlet, and established a fistulous communication with the drum-cavity. There was no difficulty in extracting the hammer after having shelled the membranous coating out of the very narrow and torturous meatus. Even the cartilaginous part of the meatus was poorly developed and cramped, so that the transplantation flap had to be uncommonly small and was difficult to adjust. When the whole cavity was covered with sound granulations I made two skin transplantations—one from each forearm—at the end of the third

and fourth week respectively, and let the post-auricular wound close itself on January 12th. The case is not yet healed, but in a very good condition; there are no exuberant granulations now, and the steady growth of the epidermoid layer from different centres gives promise of a speedy and complete success.

The hearing in this case is the same as it was before the operation, and the patient, no more troubled by mastoid pain or headache, improved considerably in her general condition.

I selected these two cases for demonstration because they show that by means of the Stacke operation we are able to cure even the most obstinate and the most strangely complicated chronic otorrhœas, in which any of the hitherto practised methods would certainly have failed; ossiculectomy would have been impracticable in the first case, because the carious destruction of the ossicles had gone so far as to leave nothing of them visible from the outer meatus; in the second case, besides there being only a suspicion of caries at the long process of the anvil, the removal of this bonelet would, even from a wide meatus, have proved to be impossible on account of its osteophytic fixation. Likewise a mere opening of the antrum and the tiresome after-treatment with the leaden-nail after the old Schwartze method would have proved inefficacious, because in both cases the disease was not at all confined to this cavity, and nothing but a better drainage and facilities for cleansing would have been obtained.

In the discussion which ensued after Stacke's second report at Halle, Professor Schwartze acknowledged the merits and advantages of the new operation, but at the same time pointed out that the great difficulty and subtlety of it might, for some time at least, hinder its ready and general adoption. It is evident that an operation which shall be radical and sparing at the same time in a region so complicated and variable as the middle ear is, and surrounded by such important organs which might easily be imperilled, requires a most thorough knowledge of every anatomical detail and of all possible variations. But every otologist ought, and is supposed, to possess this knowledge, and will readily be inclined to devote his time and interest to the study of such a promising operation. The greater difficulty lies, methinks, in the after-treatment, which requires great patience, the highest specialistic skill and judgment, and a good deal of experience, to overcome all the innumerable and almost indescribable emergencies which are apt to postpone or defeat the final result.

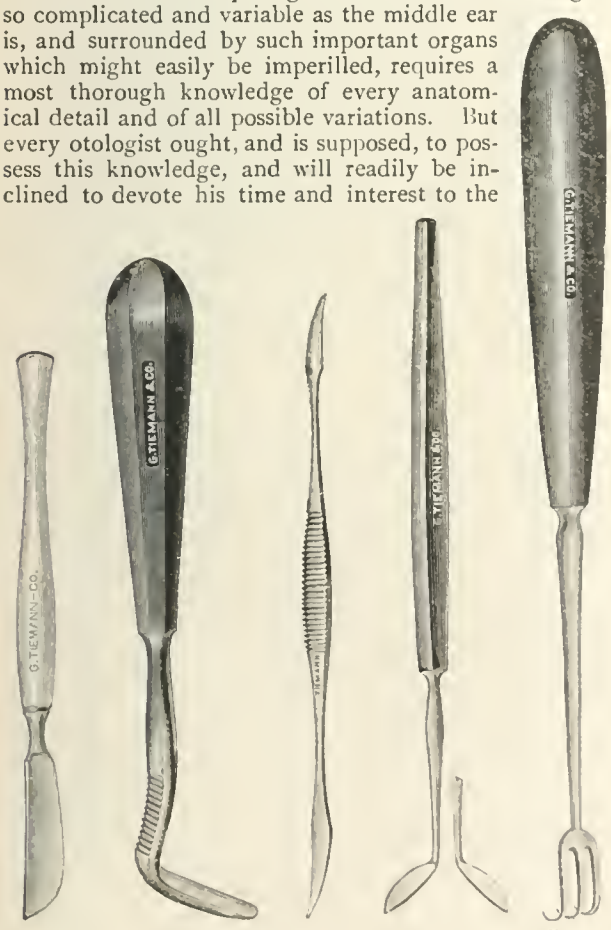

Fig. 1. Fig. 2. Fig. 3. Fig. 4. Fig. 5.

I am indebted to Messrs. Tiemann & Co. for having, after my suggestions, composed a set of instruments which will be found serviceable for the Stacke, as well as for any other kind of mastoid operation. The aseptic case with polished wood-lining contains: Fig. 1. A strong scalpel for the primary mastoid incision, by which the auricle is detached and the periosteum divided. Figs. 2 and 3. A short, strong periosteum-levator for denuding the mastoid cortex, and a double-pointed, slender one for peeling off the cutaneous coating of the meatus. Fig. 4. Two small, angular knives for cutting the membranous canal transversely, for the right and left side respectively. As devised by the writer they seem preferable to those with curved blades which Stacke uses for the same purpose. Figs. 5 and 6. A pair of sharp-pronged strong retractors, and a blunt one with a rounded hook on one, and a slender rectangular arm on the other end. The latter serves to press the posterior wall of the membranous canal against the anterior one, if the operation is done as suggested by Panse, in cases with a wide meatus. Figs. 7 and 8. Four straight and two curved gouges of different sizes. The latter were first made after the author's design, when the straight gouges showed a tendency to slip very easily off the slanting lateral and inferior wall of the attic. They afterward proved to be very convenient for every kind of chiselling work in a greater depth, but have to be handled very carefully in order not to cut deeper than it is intended. Fig. 9. An osteotome-chisel for the excision of the posterior osseous wall of the meatus. Fig. 10. A modification of Stacke's "protector," which is lighter and somewhat more handy than the original instrument. Figs. 11 and 12. ing forceps and a stronger one (Urbantschitsch's) for the removal of the ossicles and semi-detached splinters of bone. Fig. 15. A double curette for the final clearing of the operative cavity from granulations, caseous matter, etc.

Besides these special instruments a raw-hide mallet, some artery clamp forceps, a small scapel (for the formation of the transplantation flap), a needle-holder and some strong short, curved needles are required from the instrumentarium of general surgery.

A week after the above paper was read, Dr. Blake, of Bos-

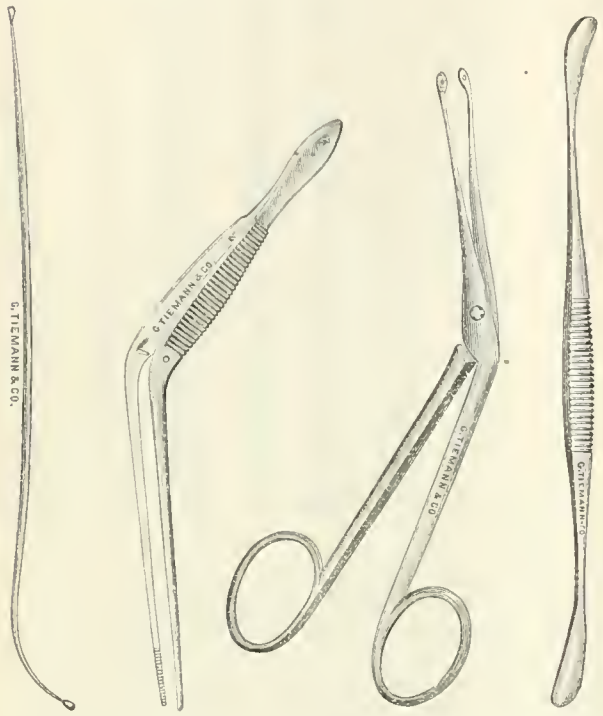

Fig. 12. Fig. 13. Fig. 14. Fig. 15.

ton, communicated, in the New York Otological Society, his experiences and results in intra-tympanic operations, particularly in ossiculectomy and mobilization or extraction of the stapes for functional purposes. His report sounded like a death knell to this long-cherished part of otosurgery. I hope that instead of it the Stacke operation may find favor with the American otologists and be practised in suitable cases. The results will be as satisfactory here, I believe, as they have been in Germany, if the encouragement as well as the warning is truly heeded, which Dr. Stacke expressed in some verses written for the author as a remembrance of their common work:

"Ruestig den Meissel geschwungen in der neuen Welt wie in der alten;
Lass aber neben dem Muth weise die Vorsicht auch walten;
Schone den 'Sinus' mit Fleiss, den 'Facialis' und andres Gelichter,
Denn sonst erntest du nur lange und schiefe Gesichter."

79 East Fifty-sixth Street.

The Abuse of Photography in Medicine.—The truth is, it seems to us, that photography is too much used in medical illustration, quite apart from considerations of decency and of the rights of the patient. It is invaluable, no doubt, within a properly restricted sphere, but most of the conditions that writers wish to show pictorially can be brought out much more tellingly in a sketch, or even a diagram. The most humiliating thing of all about the rage for photographic illustrations, lies in the undeniable fact that many writers resort to them mainly to support their statements, to establish their veracity. In plain words, they say to themselves that their clinical histories are likely to rouse incredulity, and that hence they must fortify them with pictures made with the machine that "cannot lie."—*N. Y. Medical Journal.*

THE DIAGNOSIS OF CHARCOT JOINT.

By WILLIAM B. NOYES, M.D.,

NEW YORK,

ASSISTANT IN THE DEPARTMENTS OF NERVOUS AND CHILDREN'S DISEASES, VANDERBILT CLINIC.

The subject of arthropathia tabica as a separate joint disease, caused by certain lesions in the nervous system, was much discussed some years ago, and much light was shed on its symptoms and diagnosis. The points that still remain to be settled are its real cause in the complex series of pathological changes which exist in tabes. What relation, if any, does it bear to the ataxic symptoms? Can it occur without the other symptoms of tabes, or at a time when it may assist in diagnosing tabes in its early stages?

The following case is of interest because it was necessary to diagnose a Charcot joint in a moribund patient without history in order to establish the diagnosis of the tabes dorsalis which caused it. This is a problem which might more easily occur in the practice of any general practitioner than in the clinics or private practice of those exclusively working on nervous diseases.

The patient was a man about fifty years of age whom I found in the wards of the general hospital of Vienna while taking a course there. He had been brought in the ward in the condition of coma. The urine when drawn was found to be small in amount, full of pus, and in a state of ammoniacal decomposition, indicating an old cystitis, and, there being neither paralysis nor sugar in the urine, the probable uræmic origin of the coma.

Examination of the lungs and other viscera gave negative results. Temperature not elevated. Careful examination of the reflexes proved that the knee-jerks were absent, while the reflexes of the upper extremity were preserved. The pupils failed to respond to light. This and the preceding symptom, while suggesting the existence of a possible tabes, could so easily be due to the almost moribund condition of the patient that little positive credence could be placed upon them.

One more symptom of interest remained. The right knee joint was the seat of a peculiar œdematous swelling, with evidences of fluid within the joint. Motion, especially lateral motion, was abnormally free. A backward subluxation of the joint without anchylosis was present. Crepitus could be obtained by rubbing the articular surfaces together. The joint was proved to be painless, because, while free movement of the same produced no symptoms of pain, the patient reacted promptly to needle pricks and pinching of the skin and subcutaneous tissue.

There was no history except what might be inferred from the fact that the patient seemed fairly well nourished; there was no cachexia nor evidence of severe illness, and the man had evidently recently walked. The extent of the cystitis and its involvement of the kidney proved that he must have suffered some years with bladder trouble. No disease of the prostate or urethra was found.

From these symptoms, but chiefly from the lesion of the knee joint, a diagnosis of locomotor ataxia was made. The patient died soon after, and the autopsy was made in a few hours with the following results: Heart, lungs, brain, and abdominal viscera fairly normal. The bladder was thickened, the mucous membrane giving all evidence of a severe chronic cystitis, abundant mucus and pus being present. A pyelo-nephritis of evidently recent origin, and of an extent sufficient to have caused death by uræmia, was found. Both kidneys were affected. No especial œdema or congestion of the organs.

The right knee-joint was enlarged, and filled with considerable synovial fluid, free from fibrin, pus, or blood. The synovial membrane was thickened, but showed no signs of recent acute inflammation. Ligaments and capsule loose, weakened, thickened, and otherwise changed. No loose bodies. Articular surfaces of bone much eroded, thickened, and bare of cartilage in places. There was a

backward, partial subluxation of the tibia on the femur of long standing. These were all the important pathological changes found in the joint and obviously are hardly sufficient to distinguish it absolutely from arthritis deformans, or one or two other joint lesions.

The clinical history, however, is certainly clear and unmistakable, and the general relaxation and disorganization of the joint were points of value.

To settle the question of the original tabes, I obtained the cord and certain peripheral nerves. After keeping them six weeks in Müller's fluid, I mounted and cut them. The cord had hardened so well and was so fresh that the stains used, Weigert, Pal, and carmine, gave clear indication of the extent of the healthy and diseased tissue in the cord even without a microscope. The posterior columns appeared degenerated and shrunken.

Sacral Region.—The columns of Goll were nearly normal, the column of Burdach diseased. Adopting the recent division of this column as used in Dana's "Textbook of Nervous Diseases," and in other recent works, the anterior portion or anterior root zone was normal; the median root zone showed clearly marked degeneration, increasing to the posterior root zone where the degeneration was complete, nearly all the nerve-fibres being replaced by connective tissue. The oval zone or the portion in the median line anterior to the column of Goll was normal. Lissauer's tract was decidedly affected, Everywhere there were enlarged blood-vessels penetrating the cord where vessels are not often noticed. Complete degeneration of posterior roots in this section was found.

First Lumbar Region.—Column of Goll completely degenerated, the nerve-fibres being replaced by neuroglia. In the column of Burdach, root zone normal, median root zone degenerated, except in its outer portion. Posterior root zone and Lissauer's tract less degenerated. In the lumbar region the posterior roots were less affected; the blood-vessels were still dilated, with abundance of new tissue shooting out from their walls and septa.

Middle Dorsal.—An unsymmetrical sclerosis had taken the place of all except a few nerve-fibres in the column of Goll. The column of Burdach, except the anterior root zone, was more degenerated in this region than in any parts of the cord. The posterior roots were less affected.

Upper Dorsal.—The column of Burdach was now becoming nearly normal except for a moderate degree of degeneration in the middle segment. On the other hand the column of Goll was becoming diseased, forming a wedge shaped sclerosis with hardly any nerve-fibres.

Lower Cervical.—Only the column of Goll was affected and a narrow strip of the column of Burdach, adjacent to it. The rest of the posterior column was fairly normal.

Middle Cervical.—Sclerosis was less marked but continuing distinct to the crossing of the pyramidal tracts. Posterior roots seemed nearly normal. The column of Burdach showed again signs of degeneration even with the naked eye, suggesting a beginning of the same process in the upper extremity. Medulla, pons, and brain sections absolutely normal. Anterior crural nerve sections showed partial atrophy. Optic nerve showed signs of atrophy. To sum up, there was found a fairly typical degeneration in the posterior column of the tabes type, with a certain amount of peripheral neuritis. Posterior roots degenerated in the lower half of the cord.

In looking over the literature of Charcot joint, the following points seem to be especially characteristic. A painless swelling of a joint that has reached considerable proportions in a very brief time from its onset, with no very definite cause or some slight traumatism, showing almost from its onset a chronic, not an acute or suppurative character. The surface gives a brawny, resisting sensation, like an œdema, in the immediate neighborhood of the joint, this œdema being limited to one joint unless there happen to be more than one joint affected at the same time. The skin is white, not reddened, or possibly marked with dilated veins, but there is no local heat. Crepitus is easily obtained unless masked by excess of fluid in the joint, and reappearing and remaining after the fluid subsides. The chief symptom almost invariably present is an abnormal mobility of the joint, and, if the lesion is in the knee, especially noticeable a free lateral movement of the joint.

There may soon develop peculiar deformities, subluxations leading to genu valgus or varus or other changes more or less permanent. And following or perhaps causing these deformities, absorption of the bony articular surfaces and hypertrophy of other portions not far removed, so that atrophic and hypertrophic varieties have been recognized.

Now in arthritis deformans, not unlike Charcot joint in some respects, besides the chronic history lasting for years, affecting a series of joints, especially smaller ones, it is very rare to get the abnormal laxity of joints so characteristic of arthropathia tabica, but rather abnormal stiffness. Effusion, swelling, œdema all appear late, if at all, in arthritis deformans.

There is pain, sometimes very severe, while in the Charcot joint, excepting for the lightning pains running through the entire limbs belonging to the tabes the lack of any pain in the joint is very remarkable and always noticeable.

Fractures are frequent also in the Charcot joint, and not only that, but when present soon produce an enormous excess of callous to compensate for the free motion which the lost pain sense allows the broken bone. In short, it is in the Charcot joint that you look for the rapid complete disorganization of the entire articulation, and in an infinitely shorter time than could occur in arthritis deformans These pronounced cases are rather rare. There are not many in New York to-day.

Jürgens, of Berlin, quoted by Marie,[1] states that frequently when no real arthritis exists, decided changes in the joint may still be found, or what is generally the case, overlooked. In a series of autopsies in case of tabes, he found the ligaments stretched, dilatation of vessels and other tissue changes in the synovial membranes and inter articular ligaments, and this occurring in nearly all the great joints. But in none of these were there joint lesion of an extent sufficient to permit diagnosis during life.

Marie, in the same work, has demonstrated the existence as a rule of marked changes in the bony system. Both of these are present in the average uncomplicated case of tabes, not simply when far advanced Charcot joints are found. These ordinary bone changes, in fact, have been well known for a long time.

Since the discussions of ten years ago, the French and German observers have been finding a great frequency of Charcot joints in the early preataxic stage of tabes, when the chief complaint is of the neuralgic pains, and the inco ordination has not advanced to any great extent.

Charcot in his "Leçons sur les Maladies du System Nerveux" makes the interesting statement that in many cases occurring later the joints involved are apt to be in the upper extremity which has not yet been affected by the ataxia. This is directly the reverse of the common idea. Thus, instead of having to do with peculiar trophic disturbances which occur late in a spinal cord disease, we are finding indications of processes occurring in peripheral cells and tissues, and coming it is possible, prior to any serious and extensive lesion in the cord.

There are no American statistics on autopsies of tabes in which the joint surfaces have been uniformly examined, and it is not impossible that the occurrence of these early joint changes may be found as frequent here as in France and Germany. If so the fact may be important with reference to the ataxia.

Professor James, of Harvard,[2] has made some recent and remarkably thorough investigations on the subject of muscular sense in his "Psychology," following the series of experiments and the lengthy monograph of Goldscheider, of Berlin. They hold as the result of these experiments that the muscular sense and our idea of the position of

[1] Leçons sur les Maladies de la Moelle.
[2] Principles of Psychology. Professor William James, vol. ii., p. 198.

our limbs come far more from the delicate sensations of the joint surfaces than from any other cause.

The old idea of special muscular sense or rather of the seat of this sense of position of a limb located in the muscles themselves, as held by Bell, he absolutely discards, and he believes that the muscles themselves have less to do with this sense than any other tissues of the entire limb. Bastian in his recent work, "Hysterical and Functional Paralysis," holds that the sense of position of limbs comes, 1, from conscious impressions derived from our moving members (proceeding from skin, muscles, tendons, and joints); 2, unfelt impressions emanating from the muscles in relation with their varying states of contraction. But the influence of the skin can always be eliminated by local anæsthesia, which leaves the "muscular sense" still unimpaired. Cases of anæsthesia of the skin or skin and muscles in many careful experiments in hysterical or hypnotized subjects also leave "muscular sense" unaffected. Extreme muscular dystrophies seem to have absolutely no impairment of it. The delicate sensitiveness of joint surfaces is proved by the exquisite pain in all inflammations. Goldscheider[1] pursued a series of experiments, separating the joint surfaces from one another, in normal joints and diseased, with a result of uniformly diminishing the sense of position of the limb. Anæsthesia, by whatever means induced, had no effect in changing the sense of position of the limb except when applied to the joint surface itself.

The slightest passive changes of position of joint surface, without any muscular action whatever, were always detected. But contracting muscles alone give rise to no very definite sensations. If, therefore, those early subtle changes in joint surface on which the French and German authorities previously quoted lay stress are true, this may have more to do with ataxia than has generally been believed and is certainly worth careful study.

In diseases of the cerebellum the ataxia is entirely of central origin. But in multiple neuritis the ataxia, which may be extreme, or indeed about the only symptom of the neuritis, is due only to the lesion in the peripheral nerve, or the peripheral end organs.

The ataxia of tabes is much more like the latter than the former. The more recent work in the pathology of tabes is pointing strongly to the starting point of the lesion being in the roots or peripheral nerves, and only at a later period in the cord. Many cases on record and one complete series of sections I possess in an unrecorded case prove that you can have all the symptoms of tabes extensively developed and lasting for years and yet find the most insignificant changes in the cord.

When a limb is amputated at the thigh and the cord examined some time after, a peculiar degeneration of one-half the cord corresponding to the side of the amputation is found which has a most remarkable resemblance to the degeneration found in early tabes (Kraus and Marie). This is not any ascending neuritis from infection from suppurating tissue at the periphery, but the result of an ascending Wallerian degeneration exclusively in those sensory fibres that have their cell of origin, what Marie calls "cellules ganglionnaire peripheriques," "centre trophique" situated in the periphery in muscles, tendons, skin, or joint surfaces. He says that these ought not to be called end organs, but rather cells of origin. It is the ascending degeneration from these cells that gives the peculiar results in the cord we have mentioned.

In addition to this the areas of degeneration in lesions in the posterior roots have been carefully traced out, and certainly give a remarkable counterpart of the ordinary picture of tabes sections.

That peripheral neuritis is generally present in tabes is undenied, and besides anæsthesia and other sensory disturbances it is frequently the cause of muscular atrophy, skin changes, and similar symptoms. Does peripheral neuritis alone ever cause trophic disturbances, especially of the nature of the joint lesions which we are studying?

In "Familiar Forms of Nervous Diseases," page 214, M. Allen Starr makes the following statement: "Other forms of trophic disturbance" (beside glossy skin, which he states is very frequent) "are rarely met with in multiple neuritis. It is true that inflammations of the joints resembling those appearing in acute rheumatism sometimes occur at the onset of neuritis, but as they disappear quickly while other symptoms remain, it is improbable that they are to be traced to changes in the nerves."

But are there not cases of similar arthritis on record occurring not only at the onset, but later in the course of a simple peripheral neuritis?

Weir Mitchell, in "Injuries of Nerves and their Consequences," gives a series of fifty seven cases of nerve wounds and contusions occurring in the extremities, most of them received during the battles of the Civil War. Eight or nine of these resulted in definite arthritis in the joints supplied by the injured nerves. He states, page 169, "In a certain number of nerve wounds, notably most often in those of the upper extremities, one or more joints in the wounded limb became swollen. The nature of the injury does not seem to influence the case, as I have seen it follow dislocations, ball-wounds, and contusions of nerves, while in one case it was one of the consequences of compression of the sciatic nerve by a tumor. . . . In a case at the Philadelphia Hospital a man developed extensive joint lesions owing to the brachial nerves having suffered during dislocation or upon subsequent reduction of the humerus. . . . I have since met with similar cases."

In some cases the joints of the fingers became swollen and tender, a few days after a bullet wound of the brachial plexus, but usually the swelling appeared much later, and like the glossy skin was frequently the offspring of secondary neuritis. These cases were before the days of antiseptic surgery, and some of them may have been due to simple infection of the joint. But they did not act like pyæmic joints. He states that the swelling was never very great. Redness was usually slight, and there was considerable tenderness to touch or motion. This condition remained with little change during weeks or months, but finally recovery followed in most cases.

In a pure traumatic neuritis as reported by Hausemann[1] extreme trophic changes in the joints and adjacent tissue followed injury of the sciatic nerve and a neuromatous change in the lower portion of the thigh.

In so-called anæsthetic leprosy every possible variety of trophic disturbance may occur in skin, muscle, bone, and joint, developing extreme arthritis following the inflammation of the nerve-trunk.

The *Lancet* (1890) reports cases which are not unlike the following seen recently in the Vanderbilt Clinic. A child, aged ten, who had suffered for eighteen months with a clear diphtheritic paralysis, came to the clinic with a lesion of the knee-joint of some weeks' standing, characterized by swelling, slight pain, and partial immobility. No history of rheumatism or traumatism. At least a year had intervened from the period when an infection by pathogenic element in the blood was possible. The cause was either some unknown traumatism or else the effect of the nerve-lesion, the limb being still paralyzed.

These cases indicate that arthritis may occur as one of the results of injury or disease of the nerve trunks from various causes.

Briefly to recapitulate, a Charcot joint can with a fair degree of certainty be clearly diagnosed from other joint lesions even in an extreme case without history of tabes, like the one described. It may be found so early that it may make a diagnosis possible at a time when some of the most typical symptoms of tabes have not yet made their appearance. Minor changes in the joint surfaces and adjacent tissues occur much more frequently than the definite Charcot joint disease, and probably have considerable influence over the development of the ataxia.

Lastly, it is not impossible that the peripheral nerves are an even more active element in causing the trophic joint changes than the cord itself.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, June 16, 1894.

ANNUAL MEDICAL MEETINGS.

THE annual meetings for the year 1894 of our State and National medical societies have for the most part been held. The addresses have been delivered, the papers read, the banquet attended, the Code discussed, and the officers elected. The meetings have been, as usual, pronounced "unusually successful," and we have no doubt that much benefit has accrued to the profession from them.

We note, however, that on the whole there have been a diminished attendance and fewer papers. We presume that the hard times have had their effect and have kept many physicians from taking the brief vacation which the yearly meetings afford. The leisure which comes from a less active practice does not lead the physician to more active writing however—a fact which is not surprising, for, after all, the best and most laboriously prepared articles usually come from the busiest men. The spring crop of papers has not matured in printed form as yet, so that we cannot say how valuable to our science they will prove to be. But writing papers is always of value to the writer as a self-educative process, and few men are so barren in ideas or narrow in experience that they cannot utter some helpful words. Medicine is a science so complex and so full of detail that even the commoner facts may slip from the memory. And often papers which tell us nothing new do at least revive forgotten data and teach us over again those things which we need to have constantly in our mental grasp. We do not, therefore, feel that the yearly production of hundreds of papers which, at first sight, seem to lack originality or to bear the marks of carelessness and haste are entirely without practical utility. The annual meetings are mighty factors in the post-graduate education of the physician.

THE CIVILIZATION OF CHICAGO.

WE should infer from the following notice (*Medical Stand*) that medical banquets in Chicago have not been in the past things of sweetness and light. The editor says:

"The banquet of the Chicago Academy of Medicine, in honor of the election of one of its fellows, Dr. J. B. Murphy, to the American Presidency of the Eleventh International Medical Congress, was the most successful social function which ever occurred under medical auspices in Chicago. The toasts and responses were free from the usual postprandial platitudes. The banquet was equally destitute of the stiff conventional or the boisterous—features common to medical banquets. The responses were free alike from spread eagle Americanism or foreignism, and culminated fittingly in an eloquent tribute to America by the representative of Germany, Dr. J. Zeissler. Dr. Pinckard, the chairman, Drs. G. F. Lydston, Sanger Brown, Moyer, Lagorio, and E. W. Lee deserve the thanks of the profession for demonstrating that medical banquets need neither be priggish nor coarse, but may exhibit humor without obscenity and dignity without pedantic prudishness."

We congratulate Chicago upon its new step forward along the paths of a restraining civilization. The Star of Empire will soon be so far westward that the great city by the lakes will be classed with the effete and conventional East. Plainly, Mr. Stead has not been to Chicago in vain.

THE DOCTORS.

THE esteemed contemporary *Punch* does not always seem funny at this distance from its proper atmosphere, but it is always good-natured and generally just. Its New York imitator, *Life*, is sometimes neither one nor the other, but simply scurrilous. Its recent cartoon on the "Vivisectionist" was a loathsome and cowardly performance, utterly false in its representation, mean in its insinuations and low in its intent.

DOCTORS AND THE WARD MAN.

THERE are few, if any, of the doctors in New York City who have practised ten years without having suffered from the depredations of sneak thieves. The articles taken include overcoats, hats, umbrellas, books, instruments, and table ornaments. It may be that some have been so fortunate as to recover their lost articles, but the number is few. Many have probably sent word to the police station and received visits from well fed individuals who talked vaguely of "clews," pawn-shops, etc., but who never accomplished anything. The investigation of the Police Department by the Senate Committee, now going on, reveals something of the character of these estimable "ward men" who posed as detectives. Their especial business seems to be to collect tribute from saloons and brothels, the impression has been also that they "stood in" with the thieves, and this impression is fast becoming a solid conviction as the investigation proceeds.

One of the daily papers puts the matter in this way:

"Citizens who have had occasion to call for the aid of these officers, in consequence of the loss of silverware, jewelry, or other valuables from their premises, have been puzzled to know why they were never of any use and what it was that they were driving at any away. They have not really understood what the 'ward men' were for, and the testimony before the investigating committee has disclosed that and made everything clear."

The moral is, that for the present the doctor had better watch his front-door and not waste his time on the "ward man."

Dr. Emory Lanphear, formerly editor of the *Kansas City Medical Index*, has removed to St. Louis to take the chair of surgery in the College of Physicians and Surgeons in that city.

News of the Week.

Cæsarean Sections in New York.—During the past four weeks there have been three successful Cæsarean sections by New York gynecologists—Drs. Boldt, Coe, and Dudley—all the mothers and children having been saved. Two of the cases were of unusual interest, as the operations were performed for the second time.

The Society of Alumni of Bellevue Hospital.—The following officers have been elected for the ensuing year: *President*, Dr. C. C. Barrows; *Vice-President*, Dr. Parker Syms; *Secretary*, Dr. William N. Hubbard; *Treasurer*, Dr. Robert J. Carlisle.

Dr. J. B. Hamilton was elected President of the Association of American Medical Colleges, at the annual meeting in San Francisco, and Dr. Bert Ellis Secretary.

Medical Society of New Jersey.—The one hundred and twenty-eighth annual meeting of this Society will be held at Lake Hopatcong on Tuesday and Wednesday, June 26th and 27th.

Death of Dr. Plymmon S. Hayes.—Dr. Plymmon Sanford Hayes, eldest son of the late Dr. Justin Hayes, died at his residence, Chicago, May 14, of pneumonia. Dr. Hayes was born in Ohio, December 1, 1850, and went with his parents to Chicago in 1862. He graduated from Rush Medical College in 1872. He was professor of chemistry in the Woman's Medical College from 1876 to 1883, and also occupied the chair of chemistry in the School of Pharmacy. At the time of his death he was professor of electro-therapeutics in the Chicago Polyclinic. Dr. Hayes was a member of the State Medical Society, of the American Medical Association, the Chicago Medical Society, the State Microscopical Society (at one time its president) and the Doctors' Club. He was an authority on electro-therapeutics, many of his works having been translated into French and German. He was a member of the Sons of the American Revolution. Dr. Hayes was prominently identified with religious and charitable works in Chicago. He was married in 1876 to Miss Hattie Hayden, of Washington, D.C., a daughter of Judge J. J. Hayden. He leaves a widow and three children.

Harlem Medical Association, New York.—The following officers were elected for the ensuing year: *President*, Dr. J. Gardner Smith; *Vice-President*, Dr. E. L. Cocker; *Secretary*, Dr. Henry W. Mooney; *Treasurer*, Dr. David Franklin.

Association of American Anatomists.—The sixth annual meeting of this Association was held in conjunction with the Congress of American Physicians and Surgeons, in Washington, D. C., May 29th to June 1st. The secretary reported that two members had resigned, and that three had died, namely, Drs. William Lee, of Washington; William B. Towles, of University of Virginia; and Corydon C. Ford, of University of Michigan. The officers elected for the ensuing term were: *President*, Dr. Thomas Dwight, of Harvard University; *First Vice-President*, Dr. B. G. Wilder, of Cornell University; *Second Vice-President*, Dr F. J. Shepherd, of McGill University, Montreal; *Secretary and Treasurer*, Dr. D. S. Lamb, of Army Medical Museum of Washington; *Delegate to the Congress of American Physicians and Surgeons*, Professor C L. Herrick, of Denison College, Granville, O.; *Alternate*, Dr. D. K. Shute, of Columbian University of Washington, D. C.; Dr. Theodore M. Gill, of Smithsonian Institution, Washington, D. C., was elected to the vacancy in the Executive Committee.

The following papers were read: "On the Identity of Structure of Protoplasm with that of Striped Muscle," by Dr. Carl Heitzmann, of New York City; "Some Problems Relating to Cerebral Fissures," by Dr. Wilder, of Ithaca; "A Plea for a Methodically Written Text-Book on Anatomy," by Dr. Edmond Souchon, of New Orleans; "Study of the Human Cranium," also "The Shortening of the Face-Axis in the Evolution of the Mammalia," by Dr. Harrison Allen, of Philadelphia; "Methods of Estimating the Height from Parts of the Skeleton," by Dr. Dwight, of Boston; "The Perineum and Perineal Body," by Dr. Shute, of Washington; "The Study of the Muscular Tunic of the Large and Small Intestine of Man in the Region of the Cæcum," also "A Note on the Occurrence of the Scapulo-Clavicular Muscle," by Mr. Moody; "Theoretical Anatomy of the Sympathetic System," by Dr. William Carr, of Washington; "The Female External Genital Organs, a Criticism on Current Anatomical Description," by Dr. Lamb, of Washington.

The following papers were read by title in the absence of the authors: "In our Two Years' Study of Anatomy, What Part of the Subject should be Covered in the First Year's Work; What Part in the Second?" by Dr. A. D. Bevan, of Chicago. Two papers by Professor P. A. Fish, of Ithaca, namely: "The Form and Relations of the Nerve-Cells and Fibres in Desmognathus Fusca;" and "The Terminology of the Nerve-Cell."

Professor Czerny has, it is stated, declined the offer of the chair of surgery in the University of Vienna, made to him by the Austrian government. It is believed that the reason for his refusal to accept the succession of his old master, Billroth, is the inadequacy of the laboratory and teaching equipment in the Allgemeines Krankenhaus. Not long ago Professor Erb, a colleague of Professor Czerny's at Heidelberg, also declined the offer of a chair in the University of Vienna for a similar reason.

The Prevalence of Rabies in Athens and the neighborhood is causing much alarm. A number of patients are in Paris under treatment by the Pasteur system.

The Wisconsin Medical Society met at Milwaukee. The following officers were elected: *President*, Dr. Almon Clark, of Sheboygan; *Vice Presidents*, Dr. J. A. Ballard, of La Crosse, and Dr. H. O. B. Wingate, of Milwaukee; *Secretary*, Dr. C. S. Shelden, of Madison; *Assistant Secretary*, Dr. C. M. Gould, of West Superior; *Treasurer*, Dr. S. S. Hall, of Ripon; *Censor for 1899*, Dr. N. M. Dodson, of Sheboygan. The following papers were read: Dr. W. H. Washburn, of Milwaukee, spoke on "Pyrexia," and Dr. T. H. Hay, on "Antipyretics and their Modus Operandi." "The Present Status of the Treatment of Acute Febrile Diseases by Means of Antipyretic Drugs" was treated by Dr. H. B. Sears, of Beaver Dam. "Hyperpyrexia and its Management" was the subject of Dr. G. M. Steele, of Oshkosh. "Ephemeral Pyrexia of Childhood," by Dr. H. B. Tanner, of Kaukauna, was followed by general discussion, led by Dr. W. A. Batchelor. "Uræmia" was treated

by Dr. B. J. Bill, of Genoa Junction, Dr. E. H. Townsend, of New Lisbon, and Dr. C. H. Lemon, of Milwaukee. The discussion on this subject was led by Dr. E. W. Malone, of Waukesha. Dr. J. R. Currens, of Two Rivers, and Dr. A. J. Rosenberry, of Wausau, discussed "The Principles and Ruts of the Practice of Medicine." "Stomach Catarrh and Lavage Treatment" was the subject of Dr. A. F. Heising, of Menomonie, and Dr. Almon Clark, of Sheboygan. Papers were read then on "Croupous Pneumonia in Children," by Dr. J. Noer, of Stoughton; on "Catarrhal Pneumonia," by Dr. Julia P. Kelley, of Milwaukee; a third, on "Cerebral Signs and Simulations in Pneumonia," by Dr. J. R. Barnett; the fourth, on "A Few Remarks about Water," by Dr. A. J. Hodgson, of Palmyra; and the fifth, on "Hæmophilia," by Dr. H. A. Anderson, of Pine Bluff; on "Forensic Aspects of Cranial Injuries," by Dr. J. H. Dawley, Plymouth. Dr. E. L. Bullard, of Waukesha, read a paper on "Acromegalia," a strange disorder of the sympathetic nervous system. Since 1886 only one hundred and fifteen cases have been reported. The case which Dr. Bullard furnished was an elderly woman.

The Kansas Medical Society, at their annual meeting held at Atchison, elected the following officers: *President*, W. R. Priest, of Concordia; *1st Vice-President*, George M. Gray, of Kansas City, Kan.; *2d Vice-President*, Dr. Tyler, of Clifton; *Corresponding Secretary*, G. A. Wall, of Topeka; *Treasurer*, L. Reynolds, of Holton; *Member Judicial Council*, C. A. Maguire, of Topeka. The society selected Topeka as the place for holding the next annual meeting.

The Cholera.—Throughout the winter Asiatic cholera prevailed in several of the southern and southwestern provinces of Russia and in Constantinople. In the cold months there were no cases in Western Europe, except possibly in the French departments of Finistère and Morbihan on the west coast, where the epidemic of last year had not been entirely stamped out. With the return of warm weather the disease has begun to spread westward from the western provinces of Russia; but up to this time it has not appeared in Western Europe, except in the region adjoining the Russian boundary, and in the two French departments already mentioned, where the old infection survives, and in a small district of Belgium, where a few cases have been reported. The reappearance of real cholera in Poland has been followed by the transmission of it across the Polish frontier into Northern Prussia, Silesia, and Galicia. Last week the daily number of new cases in Warsaw had risen to the neighborhood of 50, and the disease had followed the course of the Vistula River northward through Northern Prussia to the Baltic, raftsmen on that stream being the first victims. There are many centres of infection on the Russian side of the boundary, and from them the plague has made its way into Eastern Germany. In the French departments of Finistère and Morbihan—the extreme western departments of the republic—there were 23 deaths in February, 27 in March, and 38 in April. Probably a majority of these occurred in the port cities of Lorient and Quimper, where the disease prevailed last year. "I believe," said Dr. Irwin, of the Marine Hospital Bureau, on May 16th, "that cholera is more general in France and Belgium than it is reported to be." Despatches to London newspapers say that several sporadic cases have recently occurred in Paris. Thus far, cholera has not reappeared in Italy. The epidemic in Constantinople and neighboring places, which began last August in an asylum for the insane, is now dying out; but many cases are reported in Asia Minor. The spreading of the disease from Russia into Eastern Germany and Austria, and the presence of it in the western departments of France, at the beginning of the summer, indicate a probability that a considerable part of the Continent will be infected before the end of the warm season.—*New York Times.*

Dr. Philip H. Pfarre died at his home in Brooklyn on June 8th. He was twenty-five years of age, and was a graduate of the Long Island College Hospital. In October, 1893, he was appointed on the staff of the Brooklyn Hospital.

England's Aged Poor.—According to the census of 1891, there were in England and Wales 606,505 men and 765,917 women of sixty-five years of age and upward, of whom no fewer than 359,202 men and 455,283 women were in a measure supported by the parishes. Assorting this great total, the proportion of those living in towns was less than in the country, and, strange to say, the proportion of the old relieved "was greatest where population was decreasing and smallest where it was increasing." It is only natural to find that in England pauperism with the old diminishes with general progress and prosperity. Those who study vital statistics may gain a great deal from Mr. Booth's intelligent study. Taking sixty-five years as the standard, he finds that at this age thirty-seven per cent. of the old have good health, and twenty-three per cent. more are credited with "fair health," or, together, sixty per cent. At seventy there are thirty-seven per cent.; at seventy five, twenty-seven per cent.; while after eighty, "conditions are no worse."

Epidemic of Rabies in Cows.—Professor Paige, of the Amherst Agricultural College, has investigated the disease of which eleven cattle have died in Ware, and thinks it is hydrophobia, though he will submit the brains of the cattle to the Pasteur method of treatment before deciding. He says all the animals that died were of a herd chased by dogs three weeks ago, and no animal has shown signs of disease which was not bitten.

The Forty-Fifth Annual Meeting of the Indiana State Medical Society was held at Indianapolis, May 17th and 18th. The president, Dr. C. A. Daugherty, of South Bend, made an excellent impression, presiding over the sessions with a quiet dignity and accuracy in every way admirable. Upon the question of the revision of the code of ethics, now before the American Medical Association, the report of the secretary, as received from the county societies, was ordered transmitted to the secretary of the American Association without comment. An attempt was made to have an expression upon the subject by the State Society, but, though the reports from the county societies were very incomplete, many sending no reports, it was decided that the vote as recorded should stand as the best available expression of the sentiment of the profession of the State. This vote was by a very small majority in favor of revision. There were four hundred members in attendance, of whom three hundred and fifty-one registered and received badges. The officers elected for the ensuing year are as follows: *Presi-*

dent, E. S. Elder, of Indianapolis; *Vice-President*, C. S. Bond, of Richmond; *Secretary*, F. C. Woodburn, of Indianapolis; *Assistant Secretary*, K. K. Wheelock, of Fort Wayne.

Ohio State Medical Society.—The following officers were elected for the ensuing year: *President*, D. N. Kinsman, of Columbus; *1st Vice President*, C. O. Probst, of Columbus; *2d Vice President*, M. Stamm, of Fremont; *3d Vice-President*, J. C. Buckner, of Cincinnati; *4th Vice-President*, Robert Peter, of Canal Dover; *Secretary*, Thomas Hubbard, of Toledo; *Assistant Secretary*, Charles Graefe, of Sandusky; *Treasurer*, James A. Duncan, of Toledo; *Committee Finance*, term '92, F. C. Gray, of Dayton (unexpired term of Dr. Pomerine, deceased); term '94, N. P. Dandridge, of Cincinnati; *Committee Ethics*, F. C. Larimore, Mt. Vernon; *Committee Publication*, John P. Sawyer, of Cleveland; *Committee Legislation*, William B. Hamilton, of Columbus; *Committee Admissions*, W. C. Chapman, of Toledo; *Official Stenographer*, George E. Malsbary, of Cincinnati. Next place of meeting, Columbus; time, third Wednesday in May.

The "Slanting Handwriting," so dear to our grandmothers and grandfathers, has long been out of fashion in England and America. It will soon be a thing of the past in Germany. There, however, the change will not be due to æsthetic considerations; it is a sacrifice made to hygiene. An inquiry set on foot by the School Committee of Hanover, at the desire of the Prussian Minister of Education, leads to the conclusion that, while a slanting handwriting favors a crooked position of the writer, straight-up writing forces him to have his copy-book or writing-paper straight before him, and thus helps the writer to keep his body straight while writing. For this reason slanting writing is henceforth to be discouraged in German schools.—*British Medical Journal.*

Dr. S. Weir Mitchell has issued an Analytical Catalogue of his various publications; these range from 1852 to the present year. The books and papers are arranged in chronological order, and a short note is appended to each giving a summary of its contents.

Dr. Oliver Wendell Holmes is said to be writing an autobiography. He works at it an hour or two a day, and has already completed about one-half of what he intends to write. The work will not be published till after the author's death. For the first time in his long and brilliant literary career, the innumerable admirers of the genial "Autocrat" will wish that the publication of a book of his may be indefinitely delayed.

A Summer School of Neurology and Psychiatry.—A summer course of clinical and laboratory study of nervous and mental diseases is to be given for six weeks, beginning June 4th, at the Illinois Eastern Hospital for the Insane.

The New Jersey State Hospitals for the Insane.—This is the present position as to the State Hospitals for the Insane in New Jersey, and there is great desire on the part of medical men to have the governor rightly interpret the law in the appointment of new officials: "An act has been passed, and is now in the hands of the governor, which makes vacant every position in connection with the State Hospitals for the Insane; and as it provides for a non-partisan board of managers, and as this board of managers, and as this is in accordance with a suggestion made by the governor in his annual message, it is fair to presume it will become a law."

The Czar and the Next International Medical Congress.—The Czar of Russia, who has from the first shown great interest in having the next International Medical Congress meet in Russia, has signified his intention of contributing fifty thousand rubles toward the expenses of the meeting.

The Missouri Medical Society met at Lebanon. Drs. J. B. Jones, of Kansas City, and F. R. Fry, of St. Louis, made a plea for a training-school for idiots. Drs. Frank R. Fry, of St. Louis; J. B. Jones, of Kansas City; W. H. Evans, of Sedalia; A. B. Shaw, of St. Louis, and L. I. Matthews, of Carthage, were appointed a committee to memorialize the State legislature looking to the establishment of such an institution. Papers were read on: "Auto-Intoxication," by Dr. J. R. Lemen, of St. Louis; "Amputations of the Thigh," by Dr. A. H. Mersenbach, of St. Louis. The "code" question provoked a lively battle, championed by Dr. I. N. Love, for the revision, and Dr. Findley, of Deerfield, against the adoption of the majority report. After nearly every member present had been heard upon the question, the "coders" carried the day, and the secretary was instructed to advise the American Medical Association to the effect that "the old code was good enough for Missouri." The following officers were elected: *President*, Dr. J. M. Richmond, of St. Joseph; *Vice-President*, Dr. J. P. Thatcher, of Pisgah; Dr. James McComb, of Lebanon; Dr. J. N. Baskett, Hannibal; Dr. H. C. Crowell, of Kansas City; *Assistant Recording Secretary*, Dr. P. L. Kabler, of Hannibal; *Corresponding Secretary*, Dr. C. F. Wainwright, of Kansas City; *Treasurer*, Dr. C. A. Thompson, of Jefferson City. Hannibal was selected as the next place of meeting.

The North Dakota Society elected the following officers: *President*, Dr. A. B. Herrick, of Lisbon; *Vice-President*, Dr. Burroughs, of Bathgate; *Treasurer*, Dr. Rankin, of Jameston; *Secretary*, Dr. Campbell, of Fargo. The next meeting will be held at Fargo.

The Oklahoma Medical Society at its third annual session elected the following officers: *President*, Dr. E. O. Barker, of Guthrie: *Vice-President*, Dr. Cullimore, of Perry; *Treasurer*, Dr. F. J. Trader, of Council Grove; *Secretary*, Dr. C. D. Arnold, of El Reno. The fall meeting will be held at Perry.

The Michigan Medical Society elected the following officers: *President*, H. O. Walker, of Detroit; *Vice-Presidents*, V. C. Vaughn, of Ann Arbor, C. H. White, of Reed City, Mina Logue, of Adrian, C. H. McKain, of Vicksburg; *Treasurer*, W. G. Henry, of Detroit; *Secretary*, C. W. Hitchcock, of Detroit; *Members of the Judicial Committee*, Fleming Carrow, of Ann Arbor, Frank Garber, of Muskegon, and E. L. Shurley, of Detroit. The next meeting will be at Bay City.

The Tennessee Medical Society elected the following officers: *President*, Dr. F. L. Dim, of Memphis; *Vice-Presidents*, Drs. Gillespi, G. C. Savage, and D. E. Shields; *Secretary*, Dr. S. S. Crockett, of Nashville; *Treasurer*, Dr. A. Morrison, of Nashville.

Society Reports.

American Medical Association.

Forty fifth Annual Meeting, held in San Francisco, Cal., June 5, 6, 7, and 8, 1894.

THIRD DAY, THURSDAY, JUNE 7TH.

(By Telegraph to the MEDICAL RECORD.)

THE third general session was called to order by the president at half-past ten o'clock.

Report of the Committee on Revision of the Constitution.—DR. HOLTON, chairman of the Committee on Revision of the Constitution and By-laws, presented the majority report adopted by the committee. This matter was, he said, one of great and vital importance, the most important business, indeed, of any to be acted upon at this meeting of the American Medical Association, and should receive the most careful and thoughtful consideration. He warned his hearers not to confuse this with the matter of revision of the code of ethics. The latter was in great measure a sentimental matter, but this was a business proposition of vital importance to the entire association and to the medical profession in America. In deliberating upon the amendments proposed, the members of the committee had had constantly before them the questions: What will be for the best good of this association? What will serve best to increase the membership of the society and add to the subscription list of the *Journal?* What will conduce most to making the *Journal of the American Medical Association* the best medical journal published in the world and at the same time truly representative of the great society under whose direction and for whose benefit it is published?

DR. H. D. DIDAMA, of New York State, of the Committee on Revision, then presented a minority report differing in many essential particulars from that adopted by the majority. This was the signal for an exceedingly animated discussion, in which a number of members took part, and which threatened at one time to become somewhat personal in character. It was interrupted from time to time by motions to lay the whole matter on the table, but these were voted down, and finally the minority report was substituted for that of the majority of the committee first presented. A motion was now made to adopt the minority report as a whole, and on this a roll-call was demanded. The calling of the roll was proceeded with very slowly, being frequently interrupted by objections, but was finally completed, 215 votes in all having been cast. Of this number there were 151 ayes and 64 noes. As a three fourths vote is required to effect any change in the constitution of the association, the motion to adopt the amendments suggested in the minority report was defeated.

As so much time had been consumed in the discussion of these reports and in the calling of the roll, the address on surgery, which was in the order for this meeting, was dispensed with and the session was declared adjourned.

The registration list shows an attendance of 600 members, who are accompanied by about 400 ladies.

FOURTH DAY, FRIDAY, JUNE 8TH.

Report of the Committee on Revision of the Constitution.—At the opening of the final session, the discussion over the conflicting reports of the majority and minority of the Committee on Revision of the Constitution and By-laws was again started, but the members were weary of it and apparently were saving their strength for the dispute over the code question; so after a comparatively brief debate, the whole subject of constitutional revision was indefinitely postponed.

Revision of the Code of Ethics.—DR. H. D. HOLTON, of Vermont, chairman, then presented the report of the Committee on Revision of the Code of Ethics of the Association. This, like the report of the other committee on Thursday, gave rise to a heated and somewhat acrimonious discussion.

DR. DIDAMA, of New York, again made a minority report in opposition to that of the committee, and the adoption of this report was strongly urged upon the members.

DR. INGALLS, of Illinois, moved that the whole subject be laid on the table, and his motion was carried, greatly to the relief of most of those present.

The Journal of the American Medical Association.—The following resolution was introduced, and on motion was referred to the Judicial Council:

Whereas, The interests of the *Journal of the American Medical Association* require that it should command the confidence of the members of societies in affiliation with the association; and

Whereas, The *Journal of the American Medical Association* has continued to publish unethical advertisements, like those of antikamnia, labordine, and other secret nostrums, and that of the American Physicians' Sanatarium Company offering $1,000 worth of stock to physicians sending it patients; and

Whereas, The trustees of the *Journal* have defended such a course on the ground that the money from such advertisements was needed to publish such a journal as they thought creditable to the association; therefore be it

Resolved, That the various State medical societies in affiliation with this association are hereby requested to inform this association whether their members approve the policy of admitting such advertisements to the pages of the *Journal of the American Medical Association.*

A Department of Public Health.—DR. WINGATE presented the report of the Committee on the Establishment of a Department of Public Health at Washington. If it is found to be impossible to obtain legislation creating a department of health whose head shall be a cabinet officer, then in the opinion of the committee, an effort must be made to secure at least the appointment of a national sanitary officer.

DR. COCHRAN, of Alabama, suggested that there should be a conference on questions relating to public health, held annually in Washington. This suggestion having been put in the form of a motion, it was carried by a vote of the members present.

The Report of the Business Committee was read, and a suggestion made therein, to the effect that members who are in arrears for dues be allowed to continue for three years in debt to the association before their names are dropped from the rolls, was adopted.

Resolutions on the Death of Dr. Rauch, which had been presented by Dr. Montgomery, were unanimously adopted.

A communication was read from the Secretary of the Minnesota State Medical Society, inviting the members of the association in session in San Francisco to attend the meeting of the society in St. Paul, on their way to their homes in the East. The meeting will be held on the 20th, 21st, and 22d of the present month.

The usual votes of thanks to the medical profession of California and to the citizens of San Francisco, for courtesies extended to the visiting members, were passed.

Election of Officers.—The following were elected to fill the offices of the association for the coming year: *President*, Donald McLean, of Michigan; *1st Vice-president*, Starling Loving, of Ohio; *2d Vice-president*, William Warson, of Iowa; *3d Vice-president*, W. B. Rogers, of Tennessee; *4th Vice-president*, F. S. Bascom, of Utah; *Treasurer*, S. P. Newman, of Illinois; *Permanent Secretary*, W. B. Atkinson, of Pennsylvania; *Assistant Secretary*, G. H. Rohe, of Maryland; *Librarian*, no election; *Trustees*, Joseph Eastman, of Indiana, J. T. Priestly, of Iowa, J. E. Woodbridge, of Ohio, D. W. Graham, of Illinois, and J. W. Graham, of Colorado; *Members of the Judicial Council*, J. D. Crothers, of Connecticut, C. H. Gillespie, of Tennessee, W. T. Bishop, of Pennsylvania, C. H. Hughes, of Missouri, I. J. Heiberger, of the District of Columbia, and H. Brown, of

Kentucky; to deliver the Address on Medicine, W. E. Quine, of Illinois; Address on Surgery, C. A. Wheaton, of Minnesota; Address on State Medicine, H. D. Holton, of Vermont; *Chairman of the Committee on Nominations*, Jerome Cochran.

The next meeting will be held in Baltimore, Md., beginning on the first Tuesday of May, 1893. *Chairman of the Committee of Arrangements*, Julian J. Chisholm, of Maryland.

The Constitution and Code of Ethics.—Dr. Marcy, of Massachusetts, moved that all matters relating to the amendments to the constitution and to the code of ethics, now lying on the table, be taken therefrom for further consideration. Carried. Dr. Marcy then moved to postpone indefinitely the revision of the constitution. Carried. He then moved that a statement making clear the provisions of the proposed new code be published regularly in the *Journal*, so that the exact nature of the proposed changes might be thoroughly understood by all the members of the association. This motion was also carried.

The Address on State Medicine was not read, as the prolonged discussions had consumed the entire time of the session.

Dr. Donald McLean, the newly elected president, was then escorted to the platform and spoke a few words of appreciation of the honor conferred upon him.

Dr. Hibberd, the retiring president, delivered a short valedictory address, and declared the Forty-fifth Annual Meeting of the American Medical Association closed.

The Compensation of Combined Valvular Lesions.—Dr. Baccelli remarks that the general condition of the patient may be no worse where more than one valve is involved than in a lesion of a single valve. (*The British Medical Journal*) He relates two cases in illustration: 1. A man, aged forty-five, had acute rheumatism five years previously, but only complained of symptoms for a year past. Although physical examination showed the heart much enlarged, and both mitral and aortic orifices incompetent, yet when at rest the patient gave little evidence of anything being the matter with him. The pulse presented nothing characteristic. Disturbance of compensation in valvular lesions is a much more complicated problem than is usually believed. Thus a patient after influenza exhibits symptoms of a cardiac lesion previously silent, or in another accustomed to hard work the compensation suddenly breaks down without apparent sufficient cause. The anatomico pathological defect does not constitute the whole clinical picture. Murmurs at times disappear, or a fully compensated mitral stenosis may apparently present signs which should be looked upon as of ill omen, and yet they do not prove to be so. The worst damage done to the heart is when two lesions of opposite characters, such as aortic stenosis and mitral regurgitation, exist. When the lesion affecting the valves is similar, the outlook is much less serious. But because the trouble caused by the double lesion is less, it does not necessarily follow that the danger is less. Sudden syncope may occur. The real danger lies in a material and dynamic disproportion. The prognosis must be very reserved, since the capacity of compensation may cease to exist. Prophylactic measures, including the avoidance of mental excitement, too apt to be forgotten nowadays, must be attended to. Digitalis purpurea is the sovereign remedy among cardiac tonics, caffein and strophanthus being some distance behind it. Caffein, unlike digitalis, increases the heart's action. Strophanthus is used when the others fail or have to be discontinued. 2. A man aged fifty one, with no history of rheumatism, and always in good health, was seized with dimness of vision, nausea, and vomiting. He showed the physical signs of mitral and aortic stenosis. Only slight symptoms existed; he had no cough or bronchial catarrh. Here a paradox might seem to exist—namely that a stenosis of one valve was a more serious lesion than that of two.

Congress of American Physicians and Surgeons.

Third Triennial Meeting, held at Washington, D. C., May 29, 30, 31, and June 1, 1894.

(Continued from page 741.)

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

Eighth Annual Meeting, held in Washington, May 29, 30, and 31, and June 1, 1894.

First Day, Tuesday, May 29th.

Modifications of Biglow's Operation for Stone in Cases of Enlarged Prostate.—Dr. George Chismore, of San Francisco, stated, that out of 71 litholataxies made, 52 have been cases in which senile enlargement in varying degrees has been present, all but 5 requiring the catheter.

The modifications of the classical operation suggested are as follows: 1. Substituting local for general anæsthesia in cases where an anæsthetic is required. 2. Short sittings, continue crushings only so long as fragments can easily be found; wash out the pieces, and stop the moment symptoms of exhaustion, spasm of the bladder, or unusual distress occur. 3. Remove remaining pieces, after symptoms due to previous operation have subsided, as soon as they can be felt by the searcher, usually within a week, and repeat the process until the bladder is cleared.

If necessary before the operation, when there is narrowing of canal, he dilates gradually up to 16 or 18 Van Buren sound; and in his office empties the bladder, injects from one to two fluid ounces four per cent. solution of cocaine muriate: gently inserts lithotrites, seizes, and crushes the stone.

He presented the following conclusions: In all cases of stone in the bladder where senile enlargement of the prostate gland exists, the operation described affords a reasonable probability of success, provided the urethra is, or can be made, large enough to admit the instruments; that in such cases it is possible by this method, with less suffering and danger to the patient, to remove any stone that can be gotten through a perineal incision; that the results are quite as good, both as to relief or recurrence, as those attained by cutting either "high" or "low," and that, as a rule, the time required to clear the bladder is not greater than that which is necessary to recover from a supra-pubic lithotomy. Forty-eight of the calculi are herewith presented for your inspection; the remaining four, including my largest, were unfortunately lost on the occasion of moving my office.

Dr. J. William White, of Philadelphia, was much interested in the use of the local anæsthetic, and should feel like adopting Dr. Chismore's methods in the future.

Dr. Francis S. Watson, of Boston, was very doubtful as to the value of this method.

Dr. W. K. Otis, of New York, favored the supra pubic operation, because all fragments can be removed and bladder drainage can be made.

Dr. John P. Bryson, of St. Louis, thought there was danger from irritating the prostatic urethra, and in these cases he preferred to perform prostatectomy at the same time that he removed the stone.

Dr. James Bell, of Montreal, was struck with the amount of cocaine used, as he had had an accident once with cocaine in the deep urethra. He believed in the supra-pubic operation and bladder drainage.

Dr. Edward Martin, of Philadelphia, stated that it was no safer to give chloroform in cases of kidney disease than ether.

Dr. Chismore said that in several cases he had seen pallor, nervousness, restlessness, and slight cardiac failure, but not enough to stop operation when cocaine was used. He had used as much as eight ounces of the four per cent. solution at one sitting.

Dr. L. Balton Bangs, of New York, who had occupied the chair during the discussion, was called upon for his opinion, and remarked that his own experience had been that one of the cutting operations with drainage was the best. In some cases the supra-pubic tends best to accomplish the result, in others the perineal. For the perineal he used Volkman's method of dilatation of the prostatic urethra and the removal of the stone. He had found some trouble in the use of Dr. Chismore's lithotrite. In any method of operation there often were recurrences. He would like to know how the deep urethra was anæsthetized, as cocaine must be in contact with the mucous membrane six minutes to get its effect.

Castration for Hypertrophy of the Prostate.—Dr. J. William White, of Philadelphia, read the paper. In December, 1892, he requested his assistant, Dr. Kirby, to make a series of experiments on dogs, with a view of determining whether or not castration would be followed by notable atrophy of the prostate. The results showed rapid atrophy, first of the glandular and then of the muscular elements. This was so marked that he suggested in his paper that castration might be a valuable therapeutic measure in many cases of hypertrophied prostate. While the prostate is not embryologically the true homologue of the uterus, it is developed from structure quite distinct from those which form the urinary passages. And its growth is in direct relation with the sexual life of the individual.

He refers in detail to the literature of the subject since he brought the matter before the profession, and refers to three cases operated on by Dr. Haynes, of California, the first surgeon to do the operation in this country, while Dr. Raum was the first one in Europe. He refers to the case of Dr. Smith, of New York, and a case operated on by himself. The object of the paper was to bring out discussion, and the results of cases treated were very good.

Dr. Bangs, of New York, said there was another side to this question. Simple drainage will at times produce the result claimed in these cases. He had a case recently in which he decided to drain the bladder instead of this operation, and the man had since married, and copulated successfully. If sexual hyperæmia ends at eighty, why don't we get good results in hypertrophy of prostate at that age? The spermatic artery might be tied and get atrophy in that way.

Dr. Bryson, of St. Louis, reported a case of removal of both testicles at different times for tuberculosis. The case came under his care eleven years ago, with enlarged prostate and having six ounces of residual urine. Eight years ago he reported that he had been able to perform the sexual act.

The man began to urinate less frequently at night, and the prostate was very much decreased in size, the tubercular process being quiescent. In the meantime his wife had died and he married again, but was unable to copulate. Five years ago he died of general tuberculosis.

Dr. Alexander W. Stein, of New York, had seen two cases, sixty and sixty-six years old, respectively, of atrophy of the prostate after destruction of the testicle.

Dr. Martin, of Philadelphia, said in relation to the case operated on by Dr. White, that at the time of operation the prostate was the size of half an orange. Two days ago was normal.

Dr. Belfield said if arrest of sexual life is followed by atrophy of prostate, it might be possible to remove the spirit and not the body of the testicle; ligation of the spermatic artery causes necrosis in dogs. In man, on account of collateral circulation, it has not this result.

Dr. Alexander reported two cases of undescended testicles with complete loss of glandular substance, nothing but fibrous tissue remaining, as shown by microscope —failed to produce atrophy of the prostate, as shown by rectal examination.

Dr. Bangs said that sexual appetite cannot be determined by absence of the testicle. He referred to a case sent him by Dr. Vaughn, showing the result of ligating veins. In an open operation for varicocele, the operation was soon followed by pain at the time of sexual excitement, and the man continued to get worse until the testicle and cord had become very much hypertrophied. The artery had not been tied.

In concluding, Dr. White said that there were very few men living at eighty with hypertrophy of the prostate. He had thought of ligation of the artery, but in cases where he had done it for hemorrhage, after operation for varicocele, it had been followed by necrosis; the length of the urethra had diminished one and one-fourth inch in four weeks. The frequency of urination at night was the first symptom of improvement.

He thinks if castration does cause atrophy of the hypertrophied prostate, there is no reason other than purely sentimental ones, why it should not be resorted to in a great many cases.

Two of the three cases referred to by Dr. Alexander are not important, because sexual powers are retained. In both the length of the cord left after castration affects sexual power.

A Suggestion as to the Removal of Adeno-myomatous Growths from the Prostate.—Dr. Samuel Alexander read a paper on this subject, in which he called attention to the various methods which have been employed for removing prostatic hypertrophy, and stated that he favored the double incision, as recommended by Belfield. The modification suggested by Dr. Alexander consists in removing the obstructing portions of the enlarged prostate by enucleation, after stripping up the mucous membrane from the submucous tissues by means of the finger passed into the perineal opening. In one case reported by the author the patient was a man aged fifty three, who gave a history of prostatic obstruction of two years' duration. The bladder was opened above the pubes, and a perineal incision was made extending as far as the apex of the prostate. The mucous membrane of the prostatic urethra was stripped up, and the adenoid growths removed with the prostatic forceps through the lateral opening.

The advantages claimed by Dr. Alexander for this method were that the mucous membrane remained intact; that the chances of hemorrhage were greatly diminished; that the prostatic sphincter was preserved; and the greater ease with which the entire obstructing portions of the prostate can be removed.

Dr. Belfield said that hemorrhage was chiefly from the mucous membrane. With one finger in the bladder and one in the perineum we can get at the bladder.

Dr. Watson said that enucleation is not possible in every case. He agreed with Dr. Belfield that the chief point is checking the hemorrhage by the vesical pad, suggested by Dr. Keyes.

Dr. White said that there is not enough known about the amount of prostatic tissue which can be safely removed. The mortality bears a ratio to this amount.

The discussion was continued by Drs. Bryson Bell and Bangs.

Dr. Alexander thought that the amount of prostate removed had no bearing on mortality.

Rupture of the Urethra.—Dr. Francis S. Watson, of Boston, reported four cases of this nature, the first in a sailor, due to traumatism. The other three occurring during sexual intercourse. The last was followed by gangrene of scrotum and skin on the under surface of the penis, treated by skin grafting, with excellent result.

Treatment of Cystitis.—Dr. Gardner W. Allen, of Boston, read a paper with this title. Most of the cases of cystitis are of gonorrhœal origin. In non-gonorrhœal cases the cause is not always clear, but in a certain number of cases it is apparently traceable to a posterior urethral catarrh, resulting from congestion of the prostatic portion, with or without inflammation of the seminal vesicles, and brought about by prolonged and repeated sexual excitement. For remedies he used nitrate of silver, rarely stronger than one per cent., and permanganate of potash 1 to 5,000, 1 to 3,000, and 1 to 2,000. The blad-

der should be thoroughly irrigated by means of a large-sized Ultzmann syringe, increasing the strength of the permanganate of potash until it reaches 1 to 2,000. If one method did not succeed another should be tried.

Dr. Lewis, of St. Louis, asked Dr. Allen what was his distinction between a cystitis and posterior urethritis; whether the presence of the ammoniacal urine was the test. He would advise the alternating of the remedies, both by instillation and by washing Sometimes the benefit did not show until the treatment was stopped.

Dr. Watson did not remember any cases where he could trace cystitis to sexual excesses.

Dr. Martin wished to call attention to kreasol, which was a better antiseptic and less poisonous in the bladder than carbolic acid.

Dr. Allen, in closing, stated that in regard to cystitis caused by sexual excesses, he got history of frequent and painful nucleation after sexual excesses and masturbation, which set up a prostatic catarrh, which in turn produced the symptoms.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Eleventh Annual Meeting, held in Washington, D. C., May 29, 30, 31, and June 1, 1894.

First Day, Tuesday, May 29th.

Dr. Andrew H. Smith, of New York, President, in the Chair.

Dr. Smith, in his opening remarks, referred to the long list of papers to be read at the sessions of the association. He dwelt on their importance. They were all by experts in their several lines. The American Climatological Association is advancing on its pathway of usefulness, advancing with *éclat*.

Alimentation in Pulmonary Disease.—Dr. Andrew H. Smith, of New York, read a paper with this title. Alimentation always plays an important rôle in disease in general, and has a special importance in pulmonary disease. Food may have a good or bad effect, depending on assimilation of the products of digestion. As yet, we are not familiar with the *modus operandi* of blood-production. We do not know where the corpuscles are formed. For perfect assimilation of food, there must be perfect oxygenation—the latter furnished by fresh air. Unassimilated food is a source of irritation to the economy. In pulmonary disease the action of the lungs is impaired. Undigested food is useless to the economy. For perfect metabolism, the blood must be freely aërated. An intelligent study of phthisis clearly demonstrates the folly of overfeeding. We should give as little food as may be necessary. The whole tendency has been to overdo it. The old treatment of pneumonia was that of forcing food on the stomach. In pneumonia, not only were the lungs impaired, but toxæmia resulted from overfeeding. Such efforts to keep up the strength were a mistake. Harm results from crowding the vessels. By such methods double work is thrown on the heart.

What shall the diet be? All forms of food were derived originally from the vegetable kingdom; flesh food is more readily digested than carbo-hydrates. Nourishment should be given in small quantities and repeatedly. No forcing food on patients. Water may be given freely. The instinctive feeling of the patient may be relied on, as to what will keep the blood fluid.

In chronic lung disease high nutrition is necessary, as in fibroid phthisis, patients have bloodless faces and white conjunctivæ. The pabulum from the food does not get into the circulation. In such cases we have hæmoptysis sooner or later. The respiration is impaired, and no oxygen enters the blood, the oxygen so necessary for hæmatosis, as well as for the whole process of metabolism. The blood becomes poor from imperfect hæmatosis. We cannot rely wholly on flesh foods. Dyspepsia often is present. Life in the open air is of immense value in the treatment of these cases.

Speaking of his own experience, he had been most successful in using rectal injections of defibrinated blood, four ounces at a time. It was his uniform experience that the motion following an injection showed no trace of blood. It seems to be absorbed, and to him such injections were quite the equivalent of transfusion.

He cited the case of a patient at the Presbyterian Hospital, New York City, whose weight was 106 pounds. Day by day, in visiting that ward, he expected to find the bed vacant by the man's death. On November 5th he gave blood enemata at bed time. In a month the man had gained six pounds, and at the end of three months thirty-three pounds. Man left hospital apparently well. Such patients should live much in the open air.

Regarding the use of alcohol in pulmonary cases, he had yet to be convinced that it had not a nutritive value, both in acute and chronic disease. When the odor of alcohol is found in the breath, the patient is getting too much.

The Relation which Alimentation should Bear to Oxygenation in Lung Diseases.—Dr. Boardman Reed, of Atlantic City, read the paper. Regarding forced feeding, it was just as great a mistake in pulmonary as in other diseases. An excess of food is injurious. There should be a ratio between the oxygen and the food taken. Where the in-take of oxygen is large, a large amount of food will be demanded and assimilated. A patient with impaired lungs requires less food. Overfeeding does him injury, as it cannot be assimilated.

Physicians should make a study of diet. He cited several cases showing the advantages of regulated diet. A man aged thirty, an expressman, sent for him. Was taken ill in August, 1893, was seen January 19th. Had gone to bed in November. Had been fed liberally. Temperature, 101° to 102° F. Had weighed one hundred and twelve pounds two months before—then less. Nummular sputa; dulness right apex; left apex gave evidences of slight infiltration. Was in a small, badly ventilated room. He ordered open windows; wide open all day, and open six inches at night. Sponging body first with cool and later with cold water. Illness had been attended by frequent attacks of vomiting. Creosote checked it. Stomach regained its tone. Ventilation of room and sponging did great good. He was ordered a breakfast of beefsteak and salt, preceded by a tumbler of hot water. A light lunch and dinner. He showed steady gain. Temperature, at end of two weeks, 99½° F. Night sweats had disappeared; cough slight and dry; iodide of arsenic was prescribed. Painted chest over affected area with tincture of iodine. At the end of a month he had greatly improved. Kept him out-of-doors. Weight, 126 pounds; temperature, 99° F.

February 22, 1894, patient had a relapse. He had eaten a hearty meal at midday. Found moist râles. Went back to a strict dietary. May 2d, weighed 132 pounds. He looked in robust health, and returned to his work. He had had no cough for three or four weeks. No pain in chest. In short, man got more air and less food.

Diet and hygienic regimen are necessary. Under the old treatment it was constant feeding. They did not improve. We want pure blood circulating in the lungs.

When fever is present in lung cases, rest of body is necessary. Let them rest in-doors on a bed, or out-of-doors in a hammock, in the free open air. Keep patients out of-doors. By day and night let them have an abundance of air.

Certain climates are more favorable to certain cases than others. To-day, we fully realize that the climate is not of so much importance—the colder the air the better, if they can breathe it. Change of climate benefits many. It acts as a stimulant. Often a change from one climate to another is beneficial—coast to mountain and *vice versa*.

Twelve years ago, a clergyman consulted him. It was a plain case—consolidated apices. He requested him to abandon his pulpit for a year, and go into the country and

live in the open air. He got well and in a year returned to his work, and has remained well.

Discussion.—Dr. Butler said that it was his rule to have his patients lightly fed for a few days. All acute febrile diseases were attended with a suppression of digestive fluids. In a few days the body became accustomed to an abnormally high temperature and the products of bacterial activity.

Dr. Robert H. Babcock, of Chicago, said that there were two points of great importance in the papers read. Staying the waste of the nitrogenized tissues that takes place in pulmonary disease, lessens the demand for air. In lung diseases there is a lessened ability to take oxygen. In acute disease, as in acute pneumonia, we should feed our patients with milk rich in cream, as rich as they can digest. The pulmonary circulation is under much higher pressure. The pulmonary circuit is smaller than the systemic circuit. Where there is a cavity owing to pressure on the pulmonary circulation, there is always a danger of hemorrhage. Dr. Reed's paper showed the excellent effects of regulated diet.

The antipyretic action of air was well known. The Frau Reustein treatment kept patients out in the open all day. Air, fresh and cool, acts as an antipyretic, and by lessening the febrile temperature it improves the assimilative power of the patient.

Dr. Von Ruck, of Asheville, N. C., had used injections of defibrinated blood; he had noted marked improvement. In six weeks excellent results were obtained, as proven by the usual blood tests.

Dr. D. W. Prentice, of Washington, D. C., said that the amount of carbonaceous food had to be watched. He gave some remarkable results in asthma and bronchitis. An intelligent patient had experimented on himself; had had asthma frequently, threatening suffocation. He placed himself on a strict diet of lean meat and certain vegetables, but no carbonaceous food; he kept a careful record of his weight, weight of food and fluids taken, and weight of excretions. The attacks of asthma ceased; later, he returned to free diet, and in two days the attacks of asthma returned. An excess of carbonaceous elements must be eliminated by the lungs. He returned to the earlier diet, when the asthma promptly disappeared; went on free diet, reproducing the asthma. The excess of carbonaceous elements caused it.

Dr. A. Gihon, Medical Director United States Navy, mentioned the case of a marine who got well by working in the air; the bacilli disappeared.

Dr. Andrew H. Smith said that he was greatly pleased that Dr. Von Ruck's experience confirmed his in using defibrinated blood.

In reply to a question, Dr. Smith said that the blood was injected once a day, and two ounces at a time.

Systematic Exercise in the Prevention of Phthisis.—The third paper was read by Dr. Glentwood R. Butler, of Brooklyn, N. Y. Its title was "The Methods and Value of Supervised Exercises and Diet in the Prophylaxis of Pulmonary Phthisis."

He defined pulmonary tuberculosis as a disease of nutrition—a microbian affection. Certain people showed a vulnerability of the tissues; the tissues in the human body vary in their resistance to the invasion of the bacilli. He said that special medication in phthisis was a chimera. Many things must be considered: climate, abode, personal hygiene, exercise, and its corollary, rest. As to diet, any device that will fortify the cells and body should be employed. Reinforcements should be sent to the besieged. Regulated exercise was necessary, patients must be told what to do, "Precision in the treatment of disease," wisely said Dr. Weir Mitchell, "that was just what was necessary." He defined the pretubercular stage, and that of incipient phthisis.

Hæmoptysis, he said, was pathognomonic. Exercise general and local was necessary, thereby increasing the strength aud bulk of the muscles. There was better action of the skin. Next improved digestion.

Neuro-muscular training he described at length. It improves the system. It strengthens the muscles of inspiration and expiration. Promotes an exchange of gases. Pulmonary exercise brings the vital forces of the lungs to their maximum. It means increased pulmonary expansion. Deep breathing several times a day was of great value. General exercise within fatigue. More sleep followed, and then more exercise. He reported excellent results.

Dr. Otis, of Boston, warmly approved Dr. Butler's views. To-day gymnastics are applied scientifically. Yearly he saw fully five hundred young men. Careful notes were taken on each case. The vital and ordinary capacity of the chest was taken. The gymnastic exercise was taken under the observation of a skilled assistant. At the end of six months all were carefully re-examined and re-measured, when, as a rule, excellent results were gotten.

The physician interested in diseases of the chest must make a study of modern gymnastics, just as he studies the action of drugs. In applying pulmonary gymnastics the cases must be watched.

Dr. John Winter Brannan, of New York, referred to his experience in such matters while practising in Colorado. He also was in favor of pulmonary gymnastics and deep breathing. He knew of cases that left Colorado for Boston, and there underwent a course in pulmonary gymnastics, and returned to Colorado markedly improved. Its value was great.

Dr. J. B. Walker, of Philadelphia, was pleased that too much stress was not laid on the peculiar advantage of any one climate, that a change from one to another might be beneficial.

Dr. Brannan then asked Dr. Butler how expansion of the apices was produced. Dr. Butler gave an explanation and demonstration of how it could be done for apices and bases. The fourth paper, by Dr. Clarence G. Rice, of New York City, was read by title; it was "The Importance of Mouth Cleanliness in the Prevention of Disease."

AMERICAN DERMATOLOGICAL ASSOCIATION.

Eighteenth Annual Meeting, held in Washington, May 29, 30, 31, and June 1, 1894.

First Day, Tuesday, May 29th.

The address of the President having been misplaced, the session began with the reading of papers.

Thyroid Feeding in Diseases of the Skin.—Dr. George T. Jackson, of New York, read a communication with this title. He spoke of the remarkable results obtained from thyroid feeding in myxœdema; the skin ceased scaling and resumed its normal appearance; the hair grew again and the nails became sound. That in myxœdema thyroid feeding furnishes something to the body that the changed thyroid has ceased to furnish is a rational theory of its action and basis for its use. The administration of the thyroid is attended by danger to the patient's life. It seems to exert an inhibitory action on the heart. There is generally a rise of temperature, headache, nausea, vomiting, diarrhœa; marked loss of weight has been noticed. A glycerin extract, a dessicated powder, and compressed tablets were used.

Dr. Jackson prefers putting up the powder in gelatin capsules. The writer treated three cases of myxœdema, one case of ichthyosis, and one case of dermatitis exfoliativa. Case No. 1 of myxœdema was treated from November 20th to January 23d. There was an exfoliation of the skin in large flakes and frontal headache. After the cessation of the headache the thyroid was renewed in two-grain doses. On January 23d the arms and upper chest were smooth. No change in the legs. The experiment was not resumed as the patient was confined to the house with a chronic bronchitis.

In the second case of myxœdema, after the administration of three grains t.i.d., there was headache and an

acute general erythema developed. The patient complained of burning of the skin. In this case the thyroid was given from November 23d to March 9th without improvement and was discontinued.

In a case of ichthyosis, quite a pronounced one, the treatment was carried on from November 29th to February 14th. The patient was rendered more comfortable and there was less itching. The case was not seen after February 14th. In the case of dermatatis exfoliativa there was absolutely no moisture anywhere; there was intense itching. All the hair had been lost from the entire body. It was noticeable on the temperature chart that the temperature rose in the afternoon and was subnormal in the morning. There was no positive result in this case; after nearly eight weeks of thyroid treatment it was abandoned. In the five cases the following disagreeable symptoms were met with: headache, intense erythema, nausea, vertigo, rapid pulse, and sharp rise of temperature. The writer considers that the benefits from do not compensate for the disagreeable symptoms arising from it and is not inclined to continue it.

Discussion.—Dr. Fox, of New York, believed that all cases taken from the out-door department and put in bed under good diet will improve. He thought the cases of psoriasis reported by the English improved under good diet more than by the thyroid treatment.

Dr. Hyde, of Chicago remarked that the season effected an amelioration in cases of psoriasis. Dr. Hyde reported several cases treated by thyroid and concluded by saying that he did not consider the treatment worth employing.

Rare Forms of Alopecia.—Dr. Fox, of New York, read a paper by this title, limiting his remarks to folliculitis decalvans. Two very fine photographs of this disease were shown by him. He said that accidental peculiarities in different cases has given rise to various names. The disease begins with tenderness of scalp, followed by folliculitis. There is an inflammatory condition, followed by destruction of hair. The falling out of the hair is the first symptom noticed. The hair can be pulled out without pain and is surrounded by its root sheath. The crown is mainly affected. After the subsidence of hyperæmia there occurs a sinking-in of the patch. This stage resembles very much alopecia areata, but differs in the redness and the incipient atrophy. There is marked pigmentation of patch, which persists.

The disease occurs in adults and in the young. There is a very marked general nervous condition. He found the best treatment to be the use of ung. acid salicylic, ten per cent., after shaving the patch.

Dr. Zeissler called attention to the follicular elevation and roughness of scalp in this disease. The hair seemed broken off. He had found strong sulphur ointment very useful.

Dr. Hyde thought that these rare forms of alopecia areata might be forms of tuberculosis of scalp or lupus erythematosus. He did not think that all the rare forms should be grouped under the name of folliculitis decalvans. He had had good results from the use of hydrarg. ammoniat.

Dr. Fox closed the discussion by saying that some cases of lupus erythematosus resembled very much this disease, but that in folliculitis decalvans there are broken-off hairs projecting from conical elevations.

Favus of Head and Body was the title of the next communication, presented by Drs. Cantrell and Stout. Very excellent photographs were shown. The case was that of an Italian boy, aged ten. Most of the scalp and the sides of body and back were covered by the lesions.

In the discussion following Dr. Jackson thought it was very rare to see favus on the body, and mentioned a case where there was a vesicular ring on the palm and the crusts were only to be found on the back of the hand.

Dr. Zeissler spoke of a case of Kaposi's where the spores and mycelin were found in the stomach after death.

Dr. Stellwagon stated that the case reported by Dr. Cantrell had been treated with ung. sulph., and that very active treatment was needed to eliminate the favus from the body.

Dr. Hyde had found, in his experience, that the treatment of favus of the body was very long. He had found it best to change from one anti-parasitic remedy to another.

Cold as an Etiological Factor in Diseases of the Skin.—Dr. Corlett read a paper with this title. The disease occurs on dorsal surface of hand. The lesions are scaly with a well-defined margin. The eruption appears in winter and leaves with the warm weather. In one case there was a circumscribed moist patch on left wrist. It was vesicular and resembled a herpetic lesion. Other lesions were of a dusky-red color, of a bluish or purplish color. These lesions always disappear in warm climates. The patients have never suffered from chilblains. The eruption is surrounded by horse shoe shaped patches. It becomes later of a delicate rose color. He would name the affection "dermatitis hiemalis." In the treatment he applies soothing and astringent ointments. Protection from the air is necessary.

Dr. Hyde thought that similar patches were often seen and that we should be careful in attributing the affection to cold.

Dr. White thought that affections due to cold were more general and more itchy. He sees similar lesions in all seasons.

Dr. Corlett closed the discussion by saying that the affection occurred more frequently on the right hands of right handed people.

AMERICAN ORTHOPEDIC ASSOCIATION.

Eighth Annual Meeting, held at Washington, D. C., May 29, 30, and 31, and June 1, 1894.

First Day, Tuesday, May 29th.

President's Address.—Dr. A. M. Phelps, of New York, said undoubtedly the subject of modern surgical bacteriology and pathology has made and will still further make, a most decided impression upon orthopedic surgery. No pus is formed from the bacilli of tuberculosis, but the germs grow and as surely destroy new inflammatory material as do the germs of suppuration. Then we may say that the normal inflammatory material has become diseased, which may be pyogenic, or if the tubercle bacillus is present, tubercular.

To produce disease caused by germs two conditions are essential: first, inflammatory material, which is made up of embryonic cells; and second, the presence of germ life. In the absence of either such disease cannot occur.

Immediately following a slight injury nature attempts repair by means of normal inflammatory action, but should there be floating in the circulation germ life, either tubercular or pyogenic, inoculation of this area of inflammation is almost sure to take place. During the period of active inflammation the symptoms are almost identical with disease. Understanding this we can account for the ephemeral form of hip and Pott's disease. He spoke of struma as being a condition where the vital forces had less resistance than usual, and thus made the subject more liable to the development of tuberculosis than otherwise.

The process which takes place after the inoculation of the bacilli of tuberculosis produces tubercular disease unattended with pus. Pyogenic germs produce rapid purulent destruction and the formation of abscesses when tubercular cavities or foci of disease are so inoculated. That explains why a child may carry around a fluctuating tumor filled with tubercular material that remains quiescent or possibly diminishes in size, when in a single day it increases, becomes hot, and possibly painful, and very soon ruptures, with the escape of a large quantity of pus and cheesy material. Any tubercular

foci, although convalescing, may become inoculated again through the medium of milk or contaminated food.

The Past and Future of Orthopedic Surgery.—A distinction, he said, should be made between the orthopedist and the orthopedic surgeon. The former name did not fully imply all that should come under the province of the modern orthopedic surgeon, whose work should not be limited to the mechanical treatment of diseased joints, but with a clear knowledge of the etiology and pathology he should be not only the mechanic, but the operator, when occasion demanded. This branch of surgery should not only include those conditions, but fractures and dislocations, because they required the highest degree of mechanical skill. All cases requiring osteoclasis belong to the orthopedic surgeon.

Bending of the Neck of the Femur in Adolescence.—Dr. Royal Whitman, of New York, read a paper entitled "Observations on Bending of the Neck of the Femur in Adolescence," with particular reference to the diagnosis and significance of the affection.

The object of the paper was to call attention to a deformity at the hip joint that developed in adolescence under the same conditions as knock-knee, bow-leg, or flat-foot.

The affection was first described by Müller, who in 1889 reported four cases, but the deformity had attracted no attention in the country up to the present time. Dr. Whitman presented the history of four cases, with photographs and diagrams showing the appearance of the deformity in its different stages in the hope that the affection might be recognized and not, as in the cases reported, be mistaken for rheumatism, hip-disease, dislocation, tumor, or paralysis. The early symptoms were usually stiffness and discomfort about the affected joint and thigh, most marked on changing from a position of rest to activity. These symptoms were increased by long standing or walking and relieved by rest. Examination showed a prominent trochanter more or less elevated above Nélaton's line. The leg was usually rotated outward, and there was limitation of motion at the hip joint, usually in two directions only, adduction of the thigh, and inward rotation of the leg. At a later stage there was a marked limp from shortening of the leg and progressive adduction with compensatory upward tilting of the pelvis. The symptoms were explained by the character of the deformity, the prominence and elevation of the trochanter, the outward rotation, and the progressive shortening of the limb by the bending downward and backward of the neck of the femur.

In one case where the deformity was bilateral the legs were crossed so that walking was difficult. In the early stages of this disease it might be mistaken for rheumatism or hip disease. The absence of local tenderness and swelling were important points.

Later on the great elevation of the trochanter and awkwardness of patient, particularly if both limbs are affected, may cause some difficulty in eliminating dislocation, but the history should be looked into.

Prognosis.—The tendency was toward an increase of the deformity until the resistance of the compressed bone prevented further descent of the head; then the discomfort ceased, the deformity remained, and the patient accommodated himself to the new conditions, as in similar deformities of the lower extremity.

Treatment.—If seen at an early stage, no doubt the deformity might be checked by removing the exciting cause by rest, massage, and passive manipulation. If the deformity were of one side and progressive, the long traction hip splint, in combination with other measures, was indicated.

In the stage of marked deformity, particularly if of both sides, osteotomy below the trochanter, for the purpose of overcoming the adduction and outward rotation, was indicated.

A Splint for Hip-Disease.—Dr. Wallace Blanchard, of Chicago, presented a hip-splint which he called an anti-friction splint. The apparatus had been devised by him in 1872, and after more than twenty years of excellent results he felt that it could be relied upon. The splint was intended to approximately secure fixation of the hip and at the same time to exert a traction force outward and downward in an axis with the neck of the femur for the purpose of relieving the pressure in the acetabulum. He believed that the same general rule governed the pathological progress and cure of chronic joint disease, whether it be the spine or hip, or disease of any other movable articulation. Perfect immobility of the hip, he said, could not be obtained, except by apparatus that secures both sides of the body, both hips, and both legs; but by his splint or any other immovable and inflexible splint that extends from the lower angle of the scapula to the lower border of the calf of the leg on the diseased side, motion in the joint can be reduced to 2° or 3°.

His splint was composed of a long strip of soft wagon-maker's iron, known as binding, extending from the lower angle of the scapula down over the back, thigh, and leg on the affected side until within two inches of the heel. It is bent to fit the body and held in place by bands attached at the thoracic end, one just above the patella and another at the ankle. These bands are all secured with straps or buckles in front. A short strip of the same iron is riveted to the upright and bent oval to a position necessary to support a disk of firm saddler's leather three inches in diameter, the lower third of which is to rest on the anterior-superior spine of the ilium. From this pad extending downward to the outside of the knee-band is a strip of the iron bent so as not to be nearer than two inches to the outer side of the thigh at any point.

Longitudinal traction is made, adhesive straps attached to the leg and fastened to buckles on ankle hoop. The counter-longitudinal traction is made by a couple of loops of leather extending from the thoracic band to a tight leather waist-belt. Lateral traction is made from the side-bar which extends from the ilium to the knee. A high shoe is put on the unaffected side and the patient is placed on crutches. Until spasm subsided fifteen to twenty pounds of tension should be maintained, and after that only eight or nine pounds.

Conclusions: 1. It is friction that destroys the delicate tissues of repair more rapidly than nature can provide them. 2. As friction is reduced the chances of anchylosis and deformity reduce. 3. To relieve friction, traction is just as necessary as fixation, and *vice versa*.

Rarely will a recovered case be found with angular deformity or bony anchylosis, if these indications are fulfilled.

The Question of Priority in the Use of Lateral Traction for the Relief of Intra-articular Pressure.—Dr. A. M. Phelps, of New York, stated that the question of priority always dates from the time of publication, and only for this it would be possible for valuable discoveries to be appropriated by others. The question of an individual's statement in regard to a matter, without the proof of use, is absolutely invalid for the purpose of establishing priority.

Regarding the above title, he stated that in February, 1889, he read a paper before the New York Medical Society, entitled "Management of Hip and Joint Diseases from an Anatomico-pathological Basis," which paper was published in the "Transactions" of the Society for that year. It was also published in the Medical Record, May 4, 1889.

The illustrations of the lateral traction fixation splints were presented, and also a plaster-of-Paris portable bed with lateral traction attachment. The author had examined the literature upon the subject, and was of the belief that his was the first paper printed that described the application of the principle of lateral traction for the relief of intra articular pressure and fixation for hip and joint disease. Translations from the German were presented to prove his assertion of priority.

Discussion on Hip-Disease.—Dr. Lee, of Philadelphia, asked Dr. Whitman if there was ever any enlargement of the ends of the large bones in these cases.

Dr. Gillett, of St. Paul, Minn., reported the case of a girl ten years of age, who weighed one hundred and fifteen pounds, which he believed to be one of rachitic deformity of the neck of the femur. The only symptoms were slight pain and lameness. All the motions of the joint were normal except a slight resistance to abduction. He put the patient on crutches, and has her under observation at present.

Dr. Coolridge, of Chicago, asked whether in these rachitic cases there was apt to be the same change which came on during the adolescent form.

Dr. Phelps objected to the splint presented by Dr. Blanchard, because it did not extend well beyond the foot, so as to protect the diseased joint from shock and injury.

Dr. Whitman, in closing, said he did not attempt to give the etiology of the disease of which so little was known. He believed his photographs of cases were the first to be shown. All the deformities met with in adults he did not believe were due to rachitic conditions, but might arise from anything which produced weakness. As to deformity of the neck of the femur in rachitic children, he thought it rare, because the neck was short and thickened as compared to a more advanced age.

Dr. Benjamin Lee, in speaking of the lateral traction hip splint, said he and Dr. Taylor had accomplished this since 1862, by means of a strap attached to a set-screw on the stem of the long splint.

Dr. Whitman, while in favor of lateral traction, said that the cases presented by Dr. Phelps to the New York Academy of Medicine could not be said to have the same exerted. The principle was good, but the application as now presented was defective.

Dr. Weigel asked if the force exerted for the purpose of obtaining lateral traction would not irritate the soft parts too much.

Dr. Phelps, in closing, said that the lateral traction was exerted sufficient distance from the joint, that no great amount of force was required.

As to his cases spoken of by Dr. Whitman, he did not consider them fair examples, as the braces were very defective and did not fully accomplish his idea of lateral traction.

Congenital Dislocation of the Hip Associated with Spastic Paralysis, Blindness, and Defective Mental Development.—Dr. Louis A. Weigel, of Rochester, N. Y., reported the case of a male child, aged two years and four months, with the above condition. The history given him by the mother was that she had a difficult labor on account of a foot presentation. There was no asphyxia at birth, but the child had a number of convulsions during the first three days and did poorly for some months afterward. The abnormal condition of the hand became noticeable early in infancy. The boy never crept or made any attempt to stand. A violent temper was manifested.

The condition found on careful examination was a complete luxation of the left hip, which could be replaced by traction, but had to be held in place by a traction hip-splint. Blindness was due to optic neuritis and secondary atrophy. The mental development was very defective. Most a year afterward the child was able to walk, and had improved very markedly mentally.

The author was of the opinion that the spastic paralysis and feeble-mindedness were the result of a cerebral hemorrhage occurring at birth, and which subsequently produced organic changes in the brain tissue. The dislocation could not have been due to violence, as the mother was unattended in her labor and the delivery was spontaneous. Arrest of development was considered to be the cause.

A second case of congenital dislocation with the spastic paralysis was spoken of, but the mental condition was normal. The tonic contraction of the muscles of the arm were even greater in this than in the first case.

Dr. Lee said he had had a case under observation sixteen years ago, for a short time only, who only recently came to him again. The patient in the meantime had had tenotomies at the elbow and wrist for the relief of a spastic condition of the arm. Only recently pain was complained of, extending from the hip to the knee, which he was unable to say was of spastic origin or not.

Dr. Coolridge wanted to know of Dr. Weigel if he did not think the dislocation might be due to prior brain lesion, causing the spastic paralysis.

Dr. Weigel, in closing, said that he thought the condition present due to some faulty development while in utero.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-seventh Annual Meeting, held at Washington, D.C., May 30 and 31, 1894.

Detachment of the Retina.—Dr. C. S. Bull, of New York, read a paper on recent experiences in the treatment of detachment of the retina. Statistics relating to thirty-eight cases were presented, comprising age, refraction, and whether spontaneous or traumatic. Treatment: rest on back in bed, atropia, bandage, and pilocarpin or sodii bicarb. and potass. iodidi, which may do good by derivation. Division of fixed opacities in vitreous may do good; sometimes puncture.

Dr. S. Theobald asked how and where puncture of sclerotic had been made.

Dr. Bull had used a narrow Graeffe knife and punctured as near the detachment as possible, making a valvular opening in the conjunctiva at a little distance, and enlarged the wound to 2.5 or 3 mm.

Dr. G. E. de Schweinitz, of Philadelphia, had had the same experience as Dr. Bull.

Dr. Bull believed there was nothing so good as the rest cure. He would use salicylic acid instead of pilocarpin.

Dr. F. M. Wilson read a report of two cases of sympathetic inflammation, and inquired whether enucleation may cause trouble in the other eye.

Magnet Operations.—Dr. Herman Knapp reported two recent magnet operations: one an ideal success, the other a total failure. In the first case a foreign body (steel) entered the eye. Two days later irritation, incision, introduction of magnet, removal of piece of steel; discharged cured in twelve days. The second case was seen when the lens was cataractous, and no perception of light in the upper half of the field. He recommends two modifications. Make an oblique incision through the sclerotic, then hold the wound open by platinum wire suitably curved. The removal of foreign bodies by means of the strong magnet back to the anterior chamber opens up a new field in this direction.

Dr. Lambert, of New York, mentioned some complications occurring in the course of a case in his experience.

Drs. Dennett, of New York, and Dr. Kollock, of Washington, also discussed the paper.

Foreign Bodies in the Orbit.—Dr. W. B. Johnson, of Paterson, N. J., read a paper on "Foreign Bodies in the Orbital Cavity." Four cases were reported. The first was that of a piece of cherry-tree penetrating the upper eyelid and entering the orbital cavity; removed after one week. No cerebral symptoms. Resulting vision, $\frac{6}{200}$; slight ptosis and some divergence.

Case II.—Splinter of pine-wood entered near the inner canthus. Cerebral disturbance, panophthalmitis, erysipelas, and death in three weeks. Autopsy revealed meningitis, perforation of frontal lobe of cerebrum, and fracture and displacement of the orbital plate of the frontal bone.

Case III.—Stick penetrated the upper eyelid to the temporal side of the median line. Removed two days after. Now vision normal.

Case IV.—Weeds and stubble blown through eyes and lids by explosion of a cannon. Right eye destroyed;

phthisis bulbi. In left eye extensive choroidal rupture. Vision $\frac{1}{200}$; no pain or photophobia, and works as night watchman.

Dr. Knapp quoted a case where a bullet penetrated to the sclerotic and dropped down behind the choroid.

Epithelioma of the Orbit.—Dr. George C. Harlan, of Philadelphia, reported a case of epithelioma. The right eye was removed; returned in three months; then whole orbital contents removed. Also another of a sarcomatous growth filling the right orbit. History obscure; removed, and made a good recovery. A third case in a child nine years of age had been operated upon previously by Dr. Chisholm. It returned and was again removed, and quickly returned as a fungous growth; sloughing; death. The autopsy showed encroachment into cranial cavity of a mixed cell sarcoma, mostly small round cells. There was absence of glandular enlargement.

Dr. A. G. Heyl, of Philadelphia, made some remarks on the treatment of this class of growths by the aniline dyes and quoted a case where improvement was marked after the use of the yellow pyoktanin.

Dr. Johnson spoke of the action of the toxic products of erysipelas in these cases. He had had no experience with them in tumors of the orbit, but had observed one in the pharynx, where the result was favorable. He thought it should be further tried in inoperable sarcoma.

Dr. Knapp thought the growth returns just as rapidly after use of the erysipelas products.

Dr. Bull thought that in almost all these cases of rapid development the origin was in the ethmoid or sphenoid cells.

Dr. Tilley, of Chicago, by invitation, related a case in this connection, originating in the nose.

Dr. Harlan had no doubt that the origin of the first case was in the orbit, because the orbital fat was pushed before the growth.

Tumor of the Optic Nerve.—Dr. S. M. Burnett reported a case of tumor of the optic nerve which was removed, and the patient did well for several months, when cerebral symptoms developed. The autopsy showed that this tumor had its origin behind, and that the anterior part was the most recent; not truly sarcomatous, but seemed to be of embryonal origin. The changes in the nerve are due to the mechanical pressure. Attempts to remove the tumor and save the eyeball are failures.

Dr. Knapp believed it better to save the eyeball when we can, even if it is blind; he believed the growth could be removed in some cases without removing the eye, through the outer wall of the orbit.

Dr. J. A. Lippincott, of Pittsburg, Pa., discussed the question of the malignancy of these growths. Some are benign at first and may become malignant later; but others do not assume a malignant character.

Dr. Burnett, in closing, thought myxosarcoma not malignant. Some may be, but not essentially so.

Sarcoma of the Lid.—Dr. W. H. Wilmer, of Washington, D. C., reported a case of melanotic round giant-celled sarcoma of the lid with myxomatous degeneration; removed.

Halo Symptom in Glaucoma.—Dr. S. O. Richey, of Washington, D. C., read a paper on the halo symptom in glaucoma, concluding that it is produced in the media, perhaps in the aqueous or vitreous humor; comparing it to the halo around the moon. The glaucoma halo is the reverse of the lunar halo as regards color. Light reflected through crystals of sodic chloride and urea would produce this appearance.

Dr. C. A. Oliver, of Philadelphia, read a clinical and microscopical study of two cases of glaucoma associated with intraocular hemorrhages.

Dr. Theobald read an account of a case of ophthalmitis suppurativa following discission of capsular cataract.

Dr. Heyl said that he had lost an eye after discission of membranous cataract.

Dr. Knapp had had no experience of suppuration after discission of secondary cataract, and had done fifteen hundred to two thousand cases. He does not use any especial antiseptic precautions further than as in cataract. He had seen nodules on the capsular wound looking like pus, but which clear up, and in which vision becomes normal.

Dr. Theobald also reported some typical examples of subnormal accommodative power.

Dr. de Schweinitz reported a case of epithelioma of the lid simulating a meibomian cyst.

Dr. Theobald reported a case where latent hypermetropia was not revealed by the ophthalmoscope.

Muscular Asthenopia.—Dr. George W. Hale, of Nashville, Tenn., read a paper on so-called muscular asthenopia. He took the ground that these cases were not caused by muscular weakness, but by disturbances of innervation. Prisms, tenotomy, etc., were to be abandoned in a great majority of these cases.

Dr. Edward Jackson, of Philadelphia, from a study of the measurements obtained with Javal's ophthalmometer, and subsequently by other methods under full paralysis of accommodation, concluded that the corneal and total astigmatism were identical in about six per cent. of the usual run of cases of ametropia; the amount of astigmatism alone corresponding exactly in twenty two per cent., and the direction of the principal meridians in fifty-two per cent., and approximately in seventy-eight per cent. Because of the lack of correspondence between the corneal and total astigmatism, the indications of the instrument cannot be regarded as showing the amount of astigmatism to be corrected by lenses. It must take its place among the approximate tests in the practical working out of ametropia. In aphakic eyes it has a more definite and positive value.

Low-grade Cylinders in Asthenopia.—Dr. J. A. White, of Richmond, Va., read a paper on the practical value of low-grade cylinders in some cases of asthenopia. He referred to an incorrect conclusion drawn by one of the journals as founded on two papers, one by Dr. D. B. St. John Roosa, the other by Dr. T. R. Pooley. An analysis of these two papers does not warrant the conclusion drawn by the journal. He concluded with a summary of one hundred cases.

Use of Glasses in Myopia.—Dr. S. D. Risley, of Philadelphia, read a report on the value of properly adjusted glasses in arresting progressive myopia, with an analysis of 195,754 cases, collected from opticians' books and his own cases. His conclusions pointed to the arrest of the increase of myopia by the use of glasses.

Dr. H. F. Hansell, of Philadelphia, read a paper on "Hypermetropia and Heterotropia." He stated that functional esotropia is always accompanied by upward deviation.

Strabismus with Anomalous Diplopia.—Dr. C. H. Thomas, of Philadelphia, reported three cases of strabismus with anomalous diplopia, explicable by the assumption of a false fixation point from use. When the eye was used alone, the patient used the macula; when both eyes were used in conjunction, the false spot was used.

Dr. Frank W. Ring, of New York, in discussing Dr. Hale's paper, stated that the case referred to had been prescribed for by him for three years before going to Dr. Hale, and referred to other cases treated on the lines laid down by Dr. Hale, one of marked divergence, changed from permanent to periodic divergence and parallelism at will.

Dr. Lucien Howe wished to enter a mild protest against the neglect of looking after the general health. There were many cases of women whose principal occupation consisted in attending clinics, who should be sent to the gynecologist or some kindred branch for treatment.

Dr. Theobald, in discussing Dr. White's paper, stated that where astigmatism was against the rule, it might necessitate correction, but with the rule there might be no discomfort without glasses. He also agreed fully with Dr. Risley's paper. As to Dr. Thomas's subject, he had had one case of that sort lately.

Dr. S. M. Burnett stated that astigmatism against the rule is almost always lenticular, and may be due to faulty position of the lens.

Dr. Randall stated that myopia appeared to be decreasing in Philadelphia, according to the statistics. Developmental myopia is a myth as a physiological process.

Dr. Dennett called attention to a possible source of error in comparing the readings of the ophthalmometer with the results of lens tests.

Dr. J. A. Lippincott had found the observations with the ophthalmometer correct in seventy eight per cent.

Dr. Jackson had noticed an increase of astigmatism after tenotomies.

Dr. W. S. Dennett, of New York, exhibited a new mode of lighting up the disk of the ophthalmometer, also a set of verniers to assist the reading on the arc.

Dr. W. E Lambert exhibited an optometer for retinoscopy with a rod so attached that the observer can stand one metre or more away and manipulate the apparatus. The disk lenses are rotated by two rods, one moving within the other.

Dr. Randall spoke of the increase in accuracy in retinoscopy at much greater distances than one metre, with a plane mirror. At six metres the test will differentiate between 0.65 and 0.75, perhaps, even with a small pupil.

Dr C. F. Clark, of Columbus, O , reported a case of binocular coloboma of the lens, without coloboma of iris, or choroid, and with accommodation retained.

Rupture of the Lymph sheath of a Retinal Vein.—Dr. A G. Heyl presented the report of a case of rupture of the lymph sheath of a retinal vein, with protrusion of the vein through the rupture into the vitreous, and a spot of exudation apparently originating from the summit of the loop, extending back to the disk. He concluded that the cause was strong intra-venous tension, and the sheath must have been diseased. Also that the connective-tissue growth associated with this condition was caused by leucocytes following the vein and being deposited at the summit of the loop.

Colloid Disease in the Macular Region.—Dr. G. E. de Schweinitz of Philadelphia, reported a case of colloid disease in the macular region analogous in appearance to the so-called drusen in the nerve head. He also, for Dr. E. de Schweinitz, mentioned the advantages of tricresol solution, 1 to 1,000, for immersing instruments making atropia and other solutions and as a cleansing lotion perfectly aseptic. Solutions standing for three months showed no growths.

Exercise of the Retina in Amblyopia.—Dr. Charles W. Kollock, of Charleston, S. C., reported a case of amblyopia where iodide of potassium had been used up to 300 grains daily, also hydrargyrum bichloride, which was improved by trying to see and exercise of the retina.

Ectropion Uvea.—Dr. Lucien Howe, of Buffalo, N. Y., reported three cases of ectropion uvea, distinctly pedunculated, and spoke of the apparent relation between the affection and myopia, it appearing to be hardly a simple coincidence.

Dr. C. A. Oliver, of Philadelphia, showed a sketch of embolism of the central artery of the retina, a typical ophthalmoscopic picture of the condition.

Dr. Kollock reported a case of diplopia produced by a fall on the head. Unconscious three weeks. Double vision permanent. Ophthalmoscopic examination negative and sight good. Some confusion in right ear.

A paper by Dr. P. A. Callan, of New York, entitled "A Double Case of Neuro-paralytic Keratitis Lasting Ten Years," was read by title, and was followed by a paper by Dr. Lippincott on so-called ectropion complicated with ulcer of the cornea.

Dr. F. M Wilson, of Bridgeport, Conn., exhibited a vest-pocket perimeter, with its apology for existence.

Dr. Oliver presented the model of an artificial eye for practice with the ophthalmoscope in teaching refraction; also a very compact sterilizer designed by Dr. J. A. Andrews, of New York.

Dr. C F. Clark, of Columbus, O., reported a case of binocular luxation of the lens spontaneous, terminating in glaucoma with variable and not dilated pupil.

AMERICAN GYNECOLOGICAL SOCIETY.

First Day, Tuesday, May 29th —Evening Session.

The Abuse of Trachelorrhaphy.—Dr W. R. Pryor, of New York, read the paper. The question of immediate closure was not considered. Trachelorrhaphy, he said, is performed for the cure of erosions, cervical hypertrophy, cystic degeneration, sterility, subinvolution, to prevent cancer, and for reflex symptoms. These are some of the reasons given for doing the operation, doubtless there are others After taking up these points categorically, Dr. Pryor closed as follows: Emmet's teachings have been so misapplied that now a condition (laceration), which is natural to the mother, is considered pathological, and is subjected to operation. When the cervix uteri is so far advanced in disease as to require an operation, I do not believe trachelorrhaphy the preferable procedure. When the laceration is of such degree that a cosmetically perfect cervix can be secured by trachelorrhaphy, I do not consider any operation necessary. Erosion after labor requires the same treatment as in the virgin.

Hypertrophy in the parous woman needs the operation applicable to hypertrophy in the multiparous; and those other conditions of the cervix which follow labor, whether associated with a slight or severe laceration, necessitate the removal of more tissue than trachelorrhaphy secures. The great objections I have to trachelorrhaphy are, that it does not give a cervical canal of dimensions equal to the requirements of a woman who should, as she gets older, bear each successive child with greater ease and security than the preceding; it does not remove sufficient tissue where operation is indicated; and it does not appeal to me as a rational procedure, believing, as I do, that most of the cases subjected to it require no operation whatever on the cervix, inasmuch as a generous laceration is normal and necessary.

The marvel is that, seeing all mothers have torn cervices, we have not before sought the reason. The indications for performing the operation constitute the measure of its limitations, and from them may be deduced its abuse.

Dr. Byford, of Chicago, agreed with Dr. Pryor that the ordinary cervical laceration ought not to be united. If there were disease calling for operation it should be cut out—Schroeder's amputation. Deep lacerations, however, should be united primarily.

Dr. Baldy would operate on the cervix when it had become everted and eroded, as it was apt to do in more than ordinary degrees of laceration.

Dr. C. P. Noble thought the paper revolutionary. It was a startling statement that laceration of the cervix was the normal condition after childbirth. It was not in accord with observation. The assertion, too, that cancer was present chiefly in those who had borne many children, and was due thereto, was erroneous. The cases with erosion and induration which called for Schroeder's operation, formed only a small proportion of the cases of laceration requiring operative interference.

Similar views were expressed by Dr. Boker, of Boston, and Gordon, of Maine. The latter thought much harm had been done in sewing up ordinary laceration by producing stenosis and disease higher up.

Myomectomy as a Substitute for Hysterectomy.—Dr. E C Dudley, of Chicago, read this paper. The objection to hysterectomy, or removal of the uterus with the tumor, was self-evident, and raised the question whether, in a certain proportion of cases, we could not

have recourse to a substitute which should adequately remove the disease, and at the same time preserve in whole or in part the uterus and its appendages. We already had this in the abdominal operation for pedunculated myomata, and in the vaginal operation for intra uterine and submucous myomata. The incision of Kraske might have a limited application for the removal of myomata situated in the posterior walls of the uterus, near the plane of the os internum.

The special object of this communication, however, was the preservation, whenever practicable, of the reproductive organs in the surgical treatment of uterine myomata by laparotomy. Five years ago he reported a case in which the abdomen was opened, the tumor enucleated, and the cavity left in the uterus was stitched into the abdominal wound by means of catgut. These sutures approximated the margins of the visceral peritoneum covering the uterus, to the margins of the parietal peritoneum around the abdominal wound. Temporary hæmostasis was secured during the operation by rubber ligature below the plane of the os internum. After giving details of the operation, the author said he had lost two cases the first three years, but the past two years had lost none in about twenty-five cases operated upon. It was an unsettled question whether, in cases in which the appendages were sacrificed, it was desirable to try to save the diseased uterus.

Retro peritoneal and Intra-ligamentous Tumors of the Uterus and Adnexa.—Dr. W. H. Wathen, of Louisville, Ky., read a paper on this subject. A few years ago, he said, the operator on finding this form of tumor would have immediately closed the abdomen. Now, however, they were removed with more safety than ovariotomy was done twenty years ago. The author considered the pathology of such tumors and the details of operative interference. The results of the operation depended mainly upon controlling hemorrhage and successful enucleation. If practical, it was best to tie the uterine arteries well out, and care must be taken not to injure the ureters. A pair of forceps was presented intended to take a broad hold of bleeding tissue, and made dull-pointed in order to avoid injury to thin cyst walls.

Fatal Nausea and Vomiting of Pregnancy.—Dr. E. P. Davis, of Philadelphia, Pa., in a paper on this subject related three fatal cases. In two he had not seen the patients in time, or was not permitted to bring on abortion before the anæmia had become pernicious and led to blood and tissue change and heart failure. In the third the patient left his care and died in the hands of another physician. The conclusions reached were: Nausea and vomiting of pregnancy is dangerous in proportion as it induces pernicious anæmia. The condition of danger is to be recognized by studying the cases in the light thrown upon them by the pathology of anæmia. Immediately pernicious anæmia was present the condition was dangerous; and if the symptoms did not cease at once by local or other treatment, the uterus should be emptied by modern surgical methods. In the cases narrated death was preceded for a time by streaks of coffee-ground in the vomited matter, by substernal pain, by blood change, which in one case showed itself in purpuric spots; and in one, at autopsy, many organs as well as the heart were in a state of fatty degeneration.

Dr. Davis's paper was discussed by Drs. H. P. C. Wilson, Gehrung, Reynolds, Engelman, Wylie, and Jewett, all of whom agreed that the uterus should be emptied long before the condition of pernicious anæmia set in, and most of them had found it possible to stop the vomiting by local treatment of the uterus, such measures as lifting the organ, removing disease of the cervix, or dilatation.

In England it has become a fixed popular belief that travelling on trolley (electrical) railways cures rheumatism.

AMERICAN PEDIATRIC SOCIETY.

Sixth Annual Meeting, held in Washington, D. C., May 29, 30, 31, and June 1, 1894.

(Continued from p. 714.)

First Day, Tuesday, May 29th.

Congenital Constipation.—Dr. F. Huber read a paper with this title. The peculiar anatomy of infants' intestines, the many convolutions of rectum, is a mechanical cause of constipation. He narrated a case simulating volvulus, which proved to be only stoppage by impaction. The colon of the fœtus is much longer relatively than that of the adult, and being crowded into a narrow, poorly developed pelvis, so lessens motion as to cause absorption of fluids—hence, dry stools. As treatment, he advised purgatives rarely, enemata regularly.

Dr. Stowell spoke of the value of ox-gall in enemata and Dr. Fruitnight urged that more water be given. The chairman noted that osmosis is different in children as compared with adults, water being absorbed more quickly in the former.

Malignant Measles.—Dr. J. C. Wilson, of Philadelphia, reported a case of this kind. The case was that of a man thirty-seven years of age, who had measles also in his youth. This attack proved fatal on the fifth day, the patient having petechia rather than the usual bright eruption, high fever, and coma early. There were no hemorrhages on the mucous surfaces. A child of the family also had petechial spots, but recovered. The three remaining members presented measles in its ordinary form. A blood examination of the fatal case gave negative results.

The Chairman, together with Drs. Fruitnight and Stowell, spoke of the certainty of measles appearing a second or third time in the same patient irrespective of rötheln.

Dr. Rotch was sceptical about the existence of rötheln as a distinct disease.

Dr. Seibert said he had never twice diagnosed measles in the same person.

Second Day, Wednesday, May 30th.

Dr. A. Caillé in the Chair.

Etiology, Prevention, and Treatment of Rickets.—Dr. I. M. Snow, of Buffalo, read a paper based on observations among Italians. He finds the disease in its worst forms and more frequent in this race than among Anglo Americans. Transition from warm to cold climate he holds as the primary cause. While the adults change without harm, the first generation of children suffer.

Italians in their native land are not especially rachitic, but here the most marked deformities of the chest and craniotabes occur oftener than in other races. Dentition is not influenced. Most of the Italian infants are nursed in whole or part, yet are not free from rickets. The disease is rare in Egypt, India, and Japan.

Rickets in the Negro.—Dr. George N. Acker, of Washington, read the paper. Before the war rickets was uncommon, because the slave-owners saw to the proper housing and feeding of the negroes. Now they are poorly housed, fed, and clothed; hence the race is decaying. The majority of them are rachitic. The author finds rickets common in syphilitic children rather than rare, as stated by Eustace Smith. Bad air and poor assimilation he gives as chief cause. Many are fed upon ordinary adult food from the third month. Pulmonary disorders are common, but laryngismus stridulus rarely occurs. Sweating is even more pronounced than in white children, because the negro skin is richer in sudoriparous glands. Treatment: Cod-liver oil in winter; syr. hypophosphites in summer.

Congenital Rickets.—Dr. Townsend, of Boston, reported a case of this kind. The child was of healthy parentage, but the mother was in great poverty during gestation. All the long bones were markedly curved,

and both tibiæ and forearms were fractured; the tibiæ united on the eighth day, but the child died cyanotic on the ninth day.

Dr. Griffith said that he saw much of both black and white cases, but was sure that acclimatization would not hold as cause in the negro.

Dr. Holt agreed that craniotabes is rare, but Dr. Seibert and Dr. Stowell found it quite common in Polish Hebrew children.

Dr. Fruitnight found most cases of Italian parentage, fewest among the French. The Germans furnish more than the English. He finds tuberculosis or syphilis usually present.

Dr. Adams thought the teaching proper feeding should be made not only to parents and physicians, but in the public schools by lectures.

Dr. Winters believed defective assimilation more potent than climate as cause. The rachitic often became tubercular, but the converse is rare.

Dr. Northrup reported that, of the eleven hundred babies nursed out from the New York Foundling Asylum each year, those did best that were given to Italian women.

Dr. Seibert called attention to the fact that the workingman's family eats less meat than in former years; hence increased prevalence of rickets.

Drs. Holt and Winters do not rely much upon phosphorus.

Dr. Stowell said he never had prescribed it.

Dr. Koplick esteemed it highly when given with cod-liver oil or in capsules with almond oil.

Dr. Christopher favored salt baths, which increase nitrogenous output.

Dr. Carr advocated hygiene without drugs, and special care of intestinal tract that it is able to absorb fats.

Dr. Snow, in closing, noted that rickets is rarest in those people who eat little or no meat, but live on starches chiefly.

An Aid to the Sterilization of Milk.—Dr. A. Seibert, of New York, had made thirty experiments with water and with milk filtered through cotton to ascertain how few bacilli would pass through. This proved a simple household means of purifying milk preparatory to sterilizing. No cream is lost by the process, only germs and filth saved from use. Where plain milk gave 3,800 to 200,000 germs on culture-plates, the filtered specimen would show only one-quarter that number. The sugar solution for dilution should also be filtered.

Dr. Kiliani made nineteen similar experiments with microscopic provings of the findings of Dr. Seibert. The milk should be sterilized thirty minutes in winter; sixty minutes in summer. Filtration is found to be almost as good as sterilization. In absence of a sterilizer, boil the milk and keep it in a stone pot, as it will remain good a day or more.

Infantile Scurvy.—Dr. Fruitnight, of New York, narrated six cases seen by him, and gave the general history of the disease. Proprietary foods are the apparent cause in nearly all cases. Deficient alkalinity of the blood is a constant condition in the disease. Most of the cases were free from rickets.

In diagnosis, rheumatism has most often to be eliminated, and at times can only surely be distinguished by effects of anti-scorbutic treatment. The lack of heat and redness in the swollen joints points to scurvy. In peliosis rheumatica pain is also more severe than in scurvy. The cause is a deviation of the chemical composition of the blood. This may be remedied by proper diet.

Dr. Seibert had seen but two cases in four years. He preferred treating as rheumatic any doubtful case, lest changes become marked in the heart. The doctor believes it purely an infectious disease, else why are the lesions in special localities rather than the entire body?

Dr. Crandall observed that no certain order of symptoms prevails as to appearing or going away.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twentieth Annual Meeting, held in Washington, D. C., May 30 and 31, and June 1, 1894.

Dr. B. Sachs, of New York, President, in the Chair.

First Day, Wednesday, May 30th.

President's Address.—After speaking of the work done by the association, he said that from the scientific point of view clinical medicine and neurology are one and inseparable. The diseases which the neurologist is called upon to recognize and to treat are such that he must necessarily maintain a deep interest in the affections of the heart, of the liver, of the stomach, and surely of the kidneys. He cannot afford to neglect the lungs, nor even the bladder. He is asked, perhaps, a little too frequently to consider the condition of the generative organs, and he must be even better versed than the surgeon in the anatomy of nerves and muscles. The eye, the ear, and that poorest of all the special organs, the nose, have claims upon him. The entire organism is his daily concern, although he may claim to be more intimately acquainted with the structure and functions of the nervous system than with any other part. He thought it a fortunate matter that we practise a specialty which cannot and should not be divorced from general medicine. The latter does not always include neurology, but neurology is nothing without general medicine. And, likewise, not every medical man is a neurologist, but every neurologist should be a student of general medicine in the broadest sense of the term. . . . American clinicians, with very few exceptions, have not studied neurology, at least not seriously, and neurological knowledge, we all well know, does not come by intuition. The rule which excludes neurologists from general hospital service does harm to the cause of American medical science; the vast neurological material of our hospitals is not properly utilized for purposes of investigation or of instruction.

In conclusion, he referred to the conception of the "neuron" which has been evolved from recent microscopical studies as a far-reaching one, and one which will be certain to exert the greatest possible influence over the study of nervous diseases within the next decade. It is nothing new to think of the ganglion cell as a nutritive centre for the white fibre connected with it, and to know that this white fibre is apt to undergo disintegration if separated from its nutrient cell; but it is new to learn that the entire nervous system is made up of such units of nerve-structure, consisting of a nutritive cell of the white fibre that emanates from one process of this cell, and of its termination in brush-like fashion. It is new, too, that these units are connected with one another not by direct contact; that the terminal arborizations approach one another without actually coming into contact, and that these neurons connect the white and gray matter, and pass freely from one to the other, or may exist even within the gray matter alone. If the nutrient cell is destroyed, or if its influence over the fibres connected with it is interfered with, the death of this neuron is the natural result. While he thought it rather premature to allow the doctrine to upset our former conception of systemic diseases, and while we are not yet prepared, as one German author has already done, to speak of neuron diseases, it will help us to understand many combined diseases which we have not hitherto been able properly to explain. It will help also to a better understanding of the degenerations which follow disease of the gray matter, whether it be in the cortex or in the spinal cord, and it will help us to understand the development of systemic diseases of the spinal cord, the origin of which we could not explain.

Myxœdema Treated with Sheep's Thyroid.—Dr. Samuel Ayres, of Pittsburg, read a paper upon this subject. The marvellous results of this comparatively new treatment were referred to, and the statement made that

though relapses are frequent after suspending the medicine, yet the symptoms are again quickly controlled by resuming treatment, and giving an occasional dose. It was particularly advised that at the start small doses be administered—from one to three grains of desiccated powder in capsules or tabloids once or twice daily, and gradually increased to five grains three times daily, if required. Large doses at the outset have been frequently followed by dangerous symptoms.

Owing to the favorable results from thyroid in some skin diseases, obesity, and in a case of melancholia, the paper was chiefly devoted to suggestions as to the possibilities of the preparation in certain diseases non-myxœdematous, and it was recommended that it be given a careful trial in selected cases of acute dementia, mania, melancholia, epilepsy, chorea, tetanus, anæsthesia, and in erysipelas. But its indiscriminate employment was strongly discouraged.

Dr. Starr, of New York, presented five photographs of patients with myxœdema, in three of whom unmistakable improvement was shown. He had used various preparations of the gland, but there were serious objections to many of them. He had of late made satisfactory use of the cheapest preparation on the market, which is put up in the form of tabloids each containing five grains of the extract. He was often consulted on account of the mental symptoms which were in many instances prominent in this disease. He had frequently observed melancholia with suicidal tendencies. In eight there were symptoms of dementia. He had found it of use in neuroses of the menopause. In a number of cases of acromegaly only two seemed to be benefited. The headache was relieved and it produced a feeling of *bien être*. His experience with it in paralysis agitans, epilepsy, and progressive muscular atrophy was negative.

Dr. George W. Jacoby, of New York, agreed with the previous speaker. He spoke of the difficulties in the diagnosis of true myxœdema, and reported a case and presented photographs of a child, aged fourteen. There was evidence of muscular dystrophy in the lower extremities. He thought that further experience might show some relationship between these two affections.

Dr. E. D. Fisher, of New York, thought that the use of thyroid extract should be confined to the treatment of myxœdema. There was no rational indication for its administration in other diseases.

The President dissented from this view, and believed it was but fair to try this medicine empirically, as we were not as yet familiar with the true function of the thyroid gland.

Dr. F. X. Dercum, of Philadelphia, reported a case successfully treated by the extract.

Dr. L. C. Gray, of New York, stated that all animal extracts had a similar temporary effect. A number of cases of myxœdema had relapsed. He had used the thyroid extract in only one case with the usual good result.

Dr. Leonard Weber, of New York, said there was not a single case on record that had been cured.

In one case under his observation the result was remarkably good. Relapse is apt to occur unless the remedy is continued. He believed that greater and more permanent relief could be obtained by surgical means.

Dr. Walton, of Boston, mentioned a case which improved after the use of only five grains, three times a day.

The Thyroid Theory in Graves' Disease. Two Cases Treated by Thyreoidectomy.—This was the title of a paper by Dr. J. Arthur Booth, of New York. After referring to the recent investigations as to the functions of the thyroid gland and the internal administration of the thyroid extract in the treatment of myxœdema, he spoke of the various theories that had been advanced in regard to the origin of Graves' disease. Two cases that had been treated by thyreoidectomy were reported, with the following conclusions: 1. It is by no means decided that a mere excess of the thyroid secretion is the sole and essential factor in Graves' disease; but as microscopical examination has demonstrated an enormous hyperplasia of the secreting structure, it is certainly reasonable to suppose that these changes must have some profound effect both on the quantity and quality of the secretion. 2. If altered structure and not size is the test of the disease, then thyroidectomy should be considered even in those cases where there is little or no enlargement of the thyroid. 3. Cases of Graves' disease may be entirely cured by thyroidectomy.

How this is brought about is not clear as yet. It may possibly be in one of three ways, viz.: a diminution of the functional activity of the gland substance; a relief of the stretching and irritation of the sympathetic nerve-fibres; or, finally, in the removal of pressure.

Dr. J. J. Putnam, of Boston, said that in one English case reported the patient seemed to be cured after the use of thyroid extract. He spoke of two patients treated by operation. One was improved and the other died. In both the pulse was excessively rapid. He thought it better to operate early, and not to wait until the heart's action became seriously impaired.

Dr. J. Madison Taylor, of Philadelphia, had used thyroid extract in Graves' disease without any perceptible improvement. He spoke of a case occurring in a child two years of age.

Dr. W. J. Morton, of New York, believed that patients had been cured by the use of electricity. He had often seen recovery after three or four months' treatment. He preferred this to any other method.

Dr. Dercum thought it difficult to explain the favorable result occurring after operative measures, and mentioned an instance where the gland was exceedingly small.

Dr. W. A. Hammond, of Washington, asked if Dr. Morton had used any other remedy in conjunction with electricity. He (Hammond) had been accustomed to diminish the amount of fluids taken and to give digitalis or hyoscyamine, with satisfactory results.

Dr. Morton replied that he used electricity only.

The President thought many cases were curable, and referred to the case of a young woman in whom the disease developed rapidly after a sudden fright. She improved after a prolonged rest in bed, subsequently married, gave birth to a healthy child, and completely recovered from her symptoms of Graves' disease.

Dr. Booth, in closing the discussion, said that the alleged danger of the operation is not borne out by statistics. In his case the patient did well. Galvanism had been faithfully used for seven months without satisfactory results.

Experimental Investigations on the Physical and Chemical Action of the Galvanic Current upon the Living Organism, by Dr. G. W. Jacobi and Dr. F. Schwyzer, of New York.—The authors, recognizing that our scientific comprehension of the electrodynamic curative action of electricity has been obstructed by the direction as well as the manner in which electro-physiological work has thus far been carried out, think that this objection can be met by the study of the chemical and physical actions of the galvanic current upon the simplest part of the organism, the living cell. With a view to answering the question, "Does the galvanic current produce any discoverable changes, physical or microchemical, in the single cells of the body?" the authors undertook a series of experiments upon animals (frogs, rabbits, and guinea pigs) and man, the report of which is here presented in form of a preliminary communication.

The certain and positive results thus far obtained were: 1. That by passage of the galvanic current the red blood-corpuscles under the influence of the positive pole swell up and become increased in size, while under the influence of the negative pole they become crenated and shrunken. 2. That two animals being fixed back to back and a current passed through both from chest to chest, the entire blood in the animal acted upon by the positive pole will contain more than twenty per cent.

less alkali than that of the animal which has been exposed to the influence of the negative pole.

While the authors believe that the majority of cells in the living body are influenced by the cataphoric action of the galvanic current, they are not willing to express an opinion whether and to what extent the physiology of the cells is thereby altered; on the other hand, the decrease of the alkalinity of the blood by means of the current must have a very great influence upon cell-life; this is shown by other experiments which the authors have made upon spermatozoa. This influence consists in the production of a marked functional activity in the neighborhood of the cathode on account of slightly increased alkalinity, and reduced functional activity at the anode in consequence of decreased alkalinity. The results of further experiments as well as therapeutic deductions are promised in the near future.

Dr. W. J. Morton said that as for the results obtained, attributed to the cataphoric effect, they seemed to be subversive of what is usually believed and taught, for it has thus far been accepted that the tissue at the negative pole had its fluidity increased, while that at the positive pole had its fluidity decreased.

Again, as to the action of the galvanic current in producing acidity of tissue at the positive pole region and alkalinity at the negative, he welcomed the experimental evidence furnished by the reader, that we could accept that this effect extended widely into the intrapolar region and thus influenced the irritability of tissue as in anelectrotonus and katelectrotonus. This physical explanation of physiological states had first been made by von Humboldt, who attributed the increased reponse to the excitation of the negative pole to the increased alkalinity produced in an already alkaline tissue by that pole, and the decreased response to the positive pole to the fact that that pole produced an acid reaction.

The speaker would go further than this, and had already suggested as an explanation of the increased response to the positive pole in the reaction of degeneration of Erb that the muscle degenerating had an acid reaction, and therefore responded most vigorously to the acid, viz , the positive pole.

As to alkalinizing the blood electrically we might perhaps do this better by alkalies administered by the mouth, but we could not by drugs do what Dr. Jacoby had done and render a tissue less alkaline or more acid. Therefore the local action of electricity in this respect could not be otherwise effected.

Dr. Jacoby, in closing the discussion, asked the society to look upon this work in the light of a preliminary communication, as other experiments which would certainly be productive of positive results were still in progress.

A Neurological Percussion Hammer, by Dr. William C. Krauss, of Buffalo, N. Y.—In appearance the hammer resembles the ordinary percussion hammer such as is employed more especially on the Continent, and particularly in France and Germany. It is therefore primarily a hammer, and for the neurologist may be used for testing the tendon and muscular reflexes, and for percussing the spine and head. The handle being made of hard rubber it becomes warm on friction, while the head being of metal remains always cold. Thus we have the means for examining for thermoanæsthesia. The cap on the small end of the hammer head is removable and exposes a triangular-shaped spear about one sixth inch long. The other end of the head has the rounded rubber point, thus furnishing a sharp and dull point for examining for anæsthesia. The spear is divisible, one-half remaining fixed on the hammer-head, the other half slides upon a scale graduated in millimetres and inches, forming part of the handle of the hammer, making an excellent æsthesiometer; on replacing the cap and removing the cap at the large end of the hammer a camel's hair-brush is exposed, giving a soft and the metal end a hard surface for examining the sensation. Thus we have in one instrument nearly all the apparatus necessary for making an examination of a nervous case.

Non-operative Treatment of Metatarsalgia.—Dr. V. P. Gibney, of New York, read a paper with the above title. He offered as a substitute for excision of the distal end of the fourth metatarsal bone or the branch of the peroneal nerve, a boot constructed on a Spanish last, with a heel a combination of an English and a French heel. The boot thus built transfers the weight from the ball of the foot to the plantar region just back of the ball of the foot, and to the heel and that portion of the shank just anterior to the heel. The chief point he insisted on was, a snug fit around instep shank, and a rather loose toe portion. The boot is built by an orthopedic shoemaker under his direct supervision, but can be easily imitated. A number of successful cases were reported.

Dr. Charles K. Mills, of Philadelphia, had been in the habit of recommending a similar shoe as that advised by Dr. Gibney. Some cases, however, cannot be relieved by any form of shoe, as a neuritis may have become established Operative means would then become necessary.

Dr. Putnam considered it of value to make a carefully adjusted opening in the inner sole of the shoe.

OUR LONDON LETTER.

(From our Special Correspondent.)

ANNUAL MEETINGS—PATHOLOGICAL AND EPIDEMIOLOGICAL SOCIETIES—PARASITISM AND CANCER—REPORT OF COMMITTEE ON TWO SPECIMENS—SYRINGO MYELIA—TYPHOID IN A DIABETIC—TRANSIENT HÆMOGLOBINURIA—PELIOSIS RHEUMATICA—GENERAL MEDICAL COUNCIL—DEATHS OF HENRY MORLEY AND THOMAS MADDEN STONE—MEETING OF GENERAL MEDICAL COUNCIL—PRESIDENT'S ADDRESS—SIR JAMES PAGET'S GOLDEN WEDDING—PRACTITIONERS STRUCK OFF THE REGISTER—ADVERTISING MEDICAL AID ASSOCIATIONS—REGISTRATION AND CERTIFICATION OF MIDWIVES—MEDICAL SOCIETY—A DOCTOR'S HOLIDAY—A SUBJECT FOR AN ORATION.

London, May 19, 1894.

The annual meeting of the Pathological Society was held on Tuesday, when the Report of the Council was presented and officers for the ensuing year elected. The society is still in a flourishing condition and the balance of the funds above the average. There was an exhibition of interesting specimens. The report of the Morbid Growths Committee on two of Mr. Jackson Clarke's specimens of carcinoma was read. This report does not confirm Mr. Clarke's views on parasitism which I have fully explained in former letters. The specimen described by Mr. Clarke as a parasitic spore cyst lying in the epithelium of a squamous-celled carcinoma of the nasal septum is reported by the committee to be a collection of migrated leucocytes. As to the second specimen, Mr. Clarke's description of intracellular bodies having peripheral bars or granules is admitted to be correct, but the committee could not confirm the statement that certain groups of them were in a capsule within a cell; in fact the committee report that the bodies lay in the cell-protoplasm, and not in a cyst.

On Wednesday the Epidemiological Society also held its annual meeting, when Mr. Shirley Murphy, who has for a number of years been honorary secretary, was elected president to the great satisfaction of the fellows. There was an elaborate paper on the "Distribution of the Mortality from Influenza of Late Years," by Dr. Parsons, which I may perhaps refer to in a future letter, as it is impossible to give an outline of the facts in this.

At the last meeting of the Clinical Society, held on May 11th, Dr. Beevor and Mr. J. R. Dunn gave the sequel of a case of syringo-myelia which they had shown in 1883, when a special committee appointed came to the conclusion that the various lesions were due to a central nervous affection akin to Charcot's disease. In

June, 1885, all the muscles of the arms and forearms reacted to faradic and galvanic stimuli, though there was apparent wasting of the muscles on the flexor surfaces of the forearms. The muscles of the right thumb did not respond to the faradic current; those of the left did, however, as did all the internal muscles. The reactions of the muscles of the lower extremities were normal. There was no disturbance of sensation, but occasional fibrillar twitchings were observed. In 1888 the muscles of the legs and right foot were not at all wasted, but the third phalanx of each of the four toes of the right foot appeared to be dislocated on the heads of the metatarsal bones, producing a claw-shaped position as in the hands. The nails were much wasted, and disclosed atrophic conditions similar to those of the nails of the right hand. The left foot appeared normal except in respect of the toe nails, which were beginning to waste. No nerve-symptoms were apparent, and the patient's general health was good. In November, 1889, he began to suffer from pains and attacks of nausea. In January, 1891, he had several attacks of pemphigus on the dorsal and palmar surfaces of the hands, generally preceded by slight rises of temperature. In October, 1891, the wasting of the right finger-nails had increased, accompanied apparently by wasting and shortening of the terminal phalanges. No fresh changes took place except that the patellar reflexes increased, with ankle clonus on the right side. Tactile sensibility was quite normal, but sensibility to heat, cold, and pain was much impaired, and was almost absent over a considerable area of the arms, head, and chest. In the lower extremities slight spastic paralysis was remarked. Sensation of the lower limbs was unaffected, though there was a degree of ataxic gait and of unsteadiness on standing with the eyes closed and the feet together.

On March 5, 1893, he had a fainting-fit of short duration, and the next morning a difficulty in speaking. His tongue protruded toward the right side, and the lower half of his face seemed paralyzed. The right arm and leg were slightly weak, and the head was turned a little to the left side. Although he appeared to understand what was said to him, and to want to answer, he was unable to do so, his power of articulation being confined to simple words such as "yes," "no," "one," "two," etc. Knee-jerks much increased on both sides, plantar reflexes slightly. No ankle clonus. On March 7th, he had considerable difficulty in swallowing, his pupils remained dilated, but acted to light. The legs seemed to be in a state of extensor spasm, and could be flexed only with difficulty. On March 10th he lost the power of the right arm and leg, and ultimately became comatose, and died on March 12th.

Post-mortem: Old dislocations of both wrists, left shoulder, right thumb, and outer end of right clavicle were found. There were bullæ on several fingers, some finger-nails were wasted, others absent. There was hypostatic pneumonia. The right lobe of the cerebellum was smaller than the left. The lateral ventricles of the cerebrum were dilated. The left middle cerebral artery was thrombosed, and the cortex to which it went was softened. The central canal of the spinal cord was dilated in the cervical and upper regions. The dislocated joints were typical examples of osteo-arthritis and were so described by Mr. Targett, who examined them. Dr. Beevor, who had examined the spinal cord, reported that the case presented two groups of phenomena, wasting of muscles in arms and shoulders; especially affecting the intrinsic muscles of the hands, and sensory symptoms with impaired sensibility, together with trophic changes chiefly in the joints, nails, and skin. Dilatation of the central canal of the cord destroyed the ganglion cells in the anterior cornu, thus producing trophic changes and consequent deformities, especially in the arms.

A case of typhoid fever in a diabetic patient, a man aged thirty-five, next occupied attention. The fever lasted six weeks, and was without diarrhœa or other serious complication, and might almost be regarded as simple, continued fever. An opportunity was thus afforded for observing the effect of the febrile condition on the urinary excreta. Although they were diminished during the fever, the period of their greatest diminution was that of subnormal temperature which followed. Complete disappearance of sugar from the urine occurred on the fifth, sixth, and seventh days after complete cessation of the fever, when the patient's temperature averaged 97° F. On these three days there was no sugar, the greatest freedom from glycosuria occurred at a time when the needs of the body were great, and the patient was rapidly increasing in weight to replace the twenty four pounds which he had lost during his six weeks of fever. There was a certain parallelism in this case between the output of sugar and pulse-respiration ratio; as the output of carbon by the lungs increased, its output by the urine diminished. Three instances of transient hæmoglobinuria from muscular exertion without serious symptoms in healthy young men, were afterward brought forward, and it was suggested that such cases were probably allied to "functional albuminuria," and associated with a condition of abnormal delicacy of the red corpuscles. In these cases, however, the blood was healthy, but the corpuscles were destroyed by some product of the unusual muscular exercise, probably carbonic acid.

A case of peliosis rheumatica in a married woman, aged forty-one, who for some years had suffered from dyspepsia and diarrhœa, and had been much addicted to alcohol, was then related. There was no history of rheumatism, acute or chronic.

Next week the General Medical Council will be sitting, and among its business we may expect to hear more of the set made against some Irish corporations, the question of registration of midwives, and that of the medical aid associations. The outrageous attempt of a limited liability quack company to give bogus degrees must also come forward. The judgment of the magistrates in this case was appealed from, but the court confirmed the conviction, and the judge spoke of the limited company as a bogus institution. Even so slow a body as the Medical Council may be encouraged by this to put its foot down firmly.

The death of Professor Henry Morley is announced. His name has been so long known as a professor of English, that only the few remember him as otherwise. He was, however, a member of the profession, and when young, I believe, he actually practised for a short time.

Another noteworthy death is that of Thomas Madden Stone, a faithful servant of the Royal College of Surgeons for some fifty years. He was appointed assistant librarian in 1832, and became clerk in 1853. This is an important office, and he held it until 1883, when he retired, and it seemed at first as if a corner stone of the college had been removed. He will be remembered by several generations of students, especially on examination days, as a genial and important functionary.

London, May 26, 1894.

The talk of the week is of the doings of the General Medical Council, the summer session of which opened on Tuesday and has continued until now.

The president opened the sitting with an address in which he sketched the programme of the session and on some points indicated more or less definitely his own views.

Though it is usual thus to furnish an index, so to say, to the work before the members, it may be doubted whether the custom might not be wisely omitted. The council is almost always overburdened with business—some of it of little or no interest; the sittings are inordinately expensive and the time too soon consumed in speeches. There can be no necessity to give the members an outline of their work, as they all know what they have to do, and they might as well set to and do it at once as listen to an address when time is so precious. It has been calculated that the meetings of the council cost not less

than a guinea a minute. I should think that Lei R. Quain, having delivered several of these addresses, would gladly be excused in future the performance of such a perfunctory function.

On Wednesday a pleasant interruption to some of the tedious work occurred when the president proposed to send the most hearty congratulations of the council to Sir James and Lady Paget, who then celebrated their golden wedding. In this the council succeeded in expressing, for once, the sentiment of the entire profession.

The rest of the day was occupied with discipline, the result being that five practitioners were found guilty of infamous conduct in a professional respect and their names ordered to be struck off the Register. Some of the offenders were found guilty of covering unqualified practitioners, and some of a system of unprofessional and improper advertising. Two of the latter were from Australia, so colonial practitioners will learn that they are within the purview of the council, and the respectable ones will congratulate each other. One of these Australians was a female, and so lady doctors on the Register will also be glad to find the council intend to maintain the purity of the Register.

Another of the advertisers made a very bold defence. He said he was charged with advertising his name, address, and qualifications, but in the advertisements brought as evidence there was no reference whatever to his qualifications. He admitted they bore his name and address, but contended that he stood in exactly the same position as members of the staff of a large hospital, and he could name a dozen hospitals which advertised for patients. As most members of the council are or have been on the staff of large hospitals, they must know how far this assertion is true. At any rate the bold *tu quoque* availed the accused but little, for he was convicted and struck off the Register.

The question of the medical aid associations was again raised by Mr. Bryant, who regarded the acceptance of office from a trading company as infamous, and thought such companies had been wrongly registered under the Friendly Societies Act of 1875. It was remarked that Mr. Bryant voted last year against the moderate resolutions submitted by a committee appointed on this subject, but he retorted that he did so because the resolutions were too weak. Ultimately, however, he was himself too weak to stand to his guns, and withdrew his resolution. So another session this burning question has been before the council, and nothing done.

A still more burning question—that relating to midwives—came up in two forms. First, as to the registration of midwives and the danger of creating an inferior order of practitioners; the second, as to certification. There can be no doubt that some of the proposals for dealing with midwives are most objectionable. The danger of creating an inferior order is imminent, and the general practitioners throughout the country, ably led by Dr. Rentoul, are determined to oppose, tooth and nail, such a suicidal policy. Nevertheless, certain consulting men persist in an endeavor which they must see to be opposed to the wishes of the mass of the profession, if they cannot see the danger that is so patent to the many. With professional resources reduced to a bare living, it is hard for the struggling man to see those who have attained a good position engaged in an attempt to introduce inferior rivals to divide his slender income. Consulting accoucheurs who bag large fees may treat with contempt the man who lives on minute ones, and laugh at the notion of robbing him of such trifles; but these men, hard working and ill-paid as they are, may yet unite and boycott those who are so anxious to bring in an inferior order. That inferior order, if once created, might not be grateful, and then the consultants may find their occupation gone.

The question of certification of midwives was before the council in a graphic form. On the walls were hung a number of certificates or diplomas granted by certain hospitals and by the Obstetrical Society. Lying-in hospitals have for years issued certificates of attendance on their patients. The Obstetrical Society had the audacity to set up an examination and certify to the qualification of midwives, as if it were a university or state authorized corporation. I have always condemned this monstrous assumption of authority, and at last it is occupying official attention. Everyone condemns such conduct in principle, but too many are slow to act. Mr. Wheelhouse brought in a strong resolution. The parties were warned last year without effect, so he proposed to declare it infamous in a professional respect for a registered practitioner to sanction the issue of such certificates or diplomas. This was too strong a course for so weak a body, and few ventured to support it. The president made the sensible suggestion that the authors of one or two of the worst should be summoned and told they were guilty of infamous conduct in issuing them. Even this was not adopted, but after some conversation the president was requested to repeat the warning already given to certain institutions.

Considering that the council has successfully prosecuted a man who assumed the title of M.D. (Bc., meaning botanic) by authority of a limited company, and has requested the president to take steps to prevent the issue of such bogus degrees, it is difficult to see why it should not adopt the same measure in the case of these equally bogus diplomas or certificates.

The Medical Society of London has closed work for the session. The annual oration was delivered by Dr. W. M. Ord, who regaled us with an account of a holiday excursion. We accompanied him boating, fishing, perambulating, botanizing, geologizing, and on a wet day criticising some interesting books, and pronounced this "doctor's holiday" quite a success. After the oration the *conversazione* closed the session.

RESECTION OF RIB IN PYO-THORAX.

To the Editor of the Medical Record.

Sir: In your issue of June 2, 1894, Dr. Arnot Spence, in a letter directed to you, shows great indignation on account of my remarks: "The St. Louis Clinique (Arnot Spence) does not disdain to draw classical rules from the observation of even two cases," which I have made in my paper on Pyo thorax, published in the Medical Record, May 19, 1894.

In the impersonal part of his letter to you he only corroborates my views, by stating himself that "these two cases were appended simply as illustrative ones, their histories being published in full."

The value of the fourteen histories, which were appended to my reasons why resertion is the better treatment, consists, in my humble opinion, not only in a simple illustration of my stand-point, but in their unusual and interesting additional circumstances, as I could hardly expect the profession would take any interest in the histories of such cases of pyo-thorax, which were treated under ordinary circumstances.

As far as the "exceptional number" of my cases is concerned, I am sorry to say that, with Dr. Spence's kind permission, I have operated upon even one hundred and fifty cases up to date, and all I can do is to regret that my criticising friend did not have the same chances.

What the honorable St. Francis Hospital should have to do with this number I fail to understand. Until now I did not know that pyo-thorax is mainly operated upon in hospitals. I, for instance, have operated upon one hundred and nineteen cases in private practice, while in the two hospitals with which I am connected I had a chance only thirty-one times.

I have certainly not mentioned the "exceptional" number to hurt the feelings of my esteemed colleague, but to show the great prevalence of the disease in this city, and I have no doubt that surgeons of more experience have operated upon many more cases.

Dr. Spence further says that I had declared resection of a rib to be "the only successful method" of treating

pyo-thorax. This is a small error. He furthermore refers to my eleven years' practice in this country. To this I have to say, that I myself have treated pyemas by aspiration as well as by incision long before I had the good fortune to perform operations in this country, and that I had got some good results. But since I have adopted resection throughout, my results are much better.

In regard to Dr. Spence's statement, that "at the discussion of my paper at the meeting of the County Medical Society the general opinion was that free incision was all that was necessary in the majority of cases," I have to state, that of the two surgeons participating in the discussion, one was decidedly in favor of resection and the other recommended it when the intercostal space was not as wide as to let a large drainage-tube pass.

I do not know if Dr. Spence was present. If he was, his criticisms at the time of the meeting would not have been in order. If he was not, his information must have been insufficient.

In the same issue of the MEDICAL RECORD where Dr. Spence attacks me, I noticed a report of the American Surgical Association at Washington. Here I find, in the discussions following Dr. Ashhurst's paper on "Pyothorax," that Drs. C. B. Nancrede, of Ann Arbor; F. F. Prewitt, of St. Louis; F. Willard, of Philadelphia, Park, of Buffalo, etc., were decidedly in favor of primary resection.

I may add that the first sentence of the criticisms about my paper in von Bergmann's and König's *Centralblatt für Chirurgie*, in translation, reads as follows: "With his view that primary resection in the treatment of pyo-thorax is the best treatment, Beck will hardly meet with the opposition of the surgeons."

Dr. Spence admits in his letter that his views are based on the experience of other surgeons. He especially refers to a gentleman, whom I personally esteem most highly, and whose experience, as he states, "was so favorable with the free incision method, that up to the present exsection of a rib or ribs has not been found necessary."

Unhappily, I several months ago had the bad fortune to be compelled to perform resection on a girl, ten years of age, where this very same gentleman had made an incision. No recovery had taken place six months after the "free incision" was made.

CARL BECK, M.D.

NEW YORK, June 9, 1894.

Medical Items.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 9, 1894.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	2	1
Scarlet fever	101	17
Cerebro-spinal meningitis	1	2
Measles	123	6
Diphtheria	181	54
Small-pox	11	7
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

A Word to the Busy Doctor Regarding Hæmorrhoids.—In all complaints of rectal troubles, make diagnosis before you prescribe. If piles, discover what kind, whether external or internal, bleeding or not bleeding, protruding or not protruding. External, inflamed piles require, in a degree, the same treatment as internal, yet the external require an astringent which internal cannot bear. Bleeding piles need different treatment from those that do not bleed, and protruding piles special treatment, especially if they resist reduction. External piles are of two varieties: 1, External tags of skin; 2, venous tumors. External tags of skin, when inflamed, constitute one of the most painful varieties of piles. An ordinary prescription can do but little good. Ointments cannot be absorbed. The application of heat or cold is productive of more positive results; use flaxseed poultices or cloths wrung out of hot water and changed often. If heat is unpleasant to the part, apply very cold water in the same way. If an astringent is necessary, make solution of sugar of lead, bowels should be moved daily, salines as good as any. An injection of a quart of cold water will afford some relief. A radical cure consists in the removal of the tumor. Never try to push tumor inside of rectum. The treatment of internal piles is different from the class just cited. The danger from this class is hemorrhage or strangulation; either may endanger life. An indiscriminate prescription of an ointment accomplishes nothing. Far better is an application of cold water, when not protruded; an injection of cold water when not protruded but painful, gives more comfort than all the combination of ointments usually prescribed. If, when the person who is troubled with the protrusion of internal piles is directed to take a cold water injection every morning to move the bowels, to bathe the pile tumor in cold water after an evacuation, anoint the mass with plain vaseline, then push it back, and under no circumstances to use paper as a detergent, much comfort will be gotten out of these directions. If internal piles both bleed and protrude, a little different treatment is used. The hemorrhage must be looked to; when protruding an examination can be made and if no bleeding points are found the following will be found good:

℞. Vaseline..... oz. j.
Acetate lead..... gr. xx.
Pulv. opii..... gr. xv.
Balsam Peru..... dr. j.
M. et Sig.: Apply to pile after washing with cold water.

If protruding external piles are accompanied with much pain, some complication exists, usually ulceration. Washing with hot water will be found more agreeable, to be followed by the following prescription, which contributes much to relief:

℞. Cocaine..... gr. vij.
Ex. opii..... gr. xx.
Ext. belladonnæ..... gr. xvj.
Lanoline..... oz. j.
M. et Sig.: Apply after washing. Then return mass.

At bedtime use the following suppository:

℞. Iodoform..... gr. iv.
Morph. sulph..... gr. ½
M. Ft. sup. No. 1. Sig.: Insert at bedtime.

Itching is often mistaken for piles; if itching is a most prominent symptom, it will most likely be found to be pruritis. If with piles we have an itching of the surrounding parts, the following is suggested:

℞. Vaseline..... oz. j.
Ichthyol..... dr. j.
M. Sig.: Apply often.

—*Mathew's Medical Quarterly.*

A Sugar Diet for Athletes and Workingmen.—There is a reason for all things, and at last the universal habit of indulging in sweetmeats has been vindicated by Dr. Vaughan Harley in the "Proceedings of the Royal Society." Voit and Pettenkofer long ago proved that muscular work could be produced by carbohydrates, while more recently Chaveau and Kaufman, in comparing the quantities of sugar that disappeared from the blood while the muscles were contracting and while at rest, found that four times more sugar was used during the period of muscular activity. From personal experiments Dr. Harley

finds that the amount of work performed on a diet of sugar alone, for one day, is nearly the equivalent of that done on a full diet. The amount of muscular work done on a fasting day was increased two-thirds by eating about a pound (five hundred grammes) of sucrose, showing that sugar, when taken alone, is a muscle food. By adding seven ounces of sugar to a small meal, the muscle-energy-producing effect was so great that the total amount of work done was increased about one sixth, while its addition to a large meal caused about one-eighth more daily work to be done. By adding about a half-pound (two hundred and fifty grammes) to the usual meals, the muscular work done during an eight-hours' day was increased fully one-fourth. Eating sugar about four o'clock in the afternoon prevented the usual evening fatigue. In every case where other food was taken the eating of sugar caused a marked increase in the resistance to fatigue. As sugar has become nearly as cheap as flour, it need no longer be used for sweetening only, but might be used very profitably as a muscular power producing element in the daily diet of such workingmen and athletes as are blessed with good digestions.

Artificial Abortion Procured by a Woman Introducing a Flexible Sound into her Own Uterus.—A woman's self-procured abortion is described by a Russian physician in the following words: "A short time ago I was called —to a young, well-educated lady—mother of three children, who was suffering from uterine hemorrhage. Digital exploration disclosed abortion in the seventh or eighth week. The os admitted one finger. In answer to my question what the cause of abortion might be, I learned that the patient had brought it about herself, it being her daily custom to introduce a flexible sound into her uterus, so as to avoid pregnancy. As I appeared sceptical she produced the sound (No. 16) and introduced it into her uterus before my eyes. A few days before, she had introduced the sound and let it remain until pains started. As soon as the latter had subsided she reintroduced the sound. On each occasion she disinfected the instrument in two per cent. carbolic acid. We know how difficult it often is for a surgeon to introduce a sound into the uterus, especially when the portio vaginalis is much displaced. In this instance the position of the uterus was, relatively speaking, low, the portio vaginalis long, and there was no abnormal flexion between the portio and the corpus uteri. Under these conditions it was, of course, possible for the woman to introduce the sound herself. I must add that this lady had procured herself abortion in the same manner some three years ago in Sebastopol, where she had learned the method from a midwife."—*Centralblatt für Gynaekologie.*

A Field for the Medical Philanthropist.—To prevent the access of malicious microbes to open wounds is the crowning glory of modern surgery. The limitation of specific and other germs so that they cannot prey upon human beings is the foremost element of modern preventive and curative medicine. But the accomplishment of these ends calls for constant vigilance. The exercise of such vigilance is the distinguishing characteristic of the modern doctor. Now medical societies are likely to be infested with individuals whose work is destructive of society health. The repression of such pathological germs is imperative for the best development of any medical society. A good description of such pernicious microbes was given several years ago by the late Sir Andrew Clark in an address before the Clinical Society of London. We quote from the *Boston Medical Journal.* Dr. Clark said: "For one competent and conscientious worker, there are ten who are incompetent and unconscientious, and who in divers ways hinder our progress and spoil our present possessions. Intolerant of the patient and painful toil of the true worker, acute in the power of superficial observation, gifted with a certain showy versatility, quick at catching hold of new ideas, ingenious in guessing, crude in experiment, loose in therapeutic trials, hasty in speculation, strong in dogmatic assertions, accomplished in the transfiguration and use of other men's work, finding what they want wherever they seek it, unhindered by difficulties, facile in speech, ready in writing, thirsty for notice—such men, now, alas, not uncommon in medicine, beget papers so quickly they have no necessary relation to time, observation, or thought, and flood our literature with their unworthy if not unveracious lucubrations. The favorite hunting-ground of such men is therapeutics, and their favorite sport is the catching of remedies, the putting of them to new uses, and the setting forth of their successful results. These men discern no difficulties, have no failures; they can illustrate their successes by scores of cases, and explain them by the most ingenious theories. There is scarcely any limit to the extent and variety of their achievements, and as they flaunt along in the fulness of self-satisfaction they look down with pitying condescension upon those who in the straight and narrow way conscientiously toil with small success in seeking after truth and find strength and solace in their chosen task." Dr. Clark congratulated the Clinical Society of London that at the date of his writing it had repressed the bad workers, pathogenic microbes such as be described. We wish every medical society could be similarly congratulated. Certainly the health of the medical profession would be far better than it is. Has not each society surgeons and physicians of sufficient ability and nerve to apply to their own society the laws of asepsis, and when this has failed, the laws of antisepsis? The larger the society the greater the number of these "bad workers," the pathogenic microbes. Indeed, so profound has been the conviction of many that the swarms of such in the larger societies render impossible effective work, that they devote all their attention to societies small in membership, which take good care that no "bad worker" shall be admitted, or if admitted that his life shall be made so uncomfortable that he will withdraw to secure peace. Shall we conclude, then, that this evil element cannot be controlled in the larger societies? Not at all—any more than we shall conclude that a surgical operation cannot be made aseptic. In both cases we must admit the facts and act accordingly. Both call for a certain special knowledge, and unremitting care and determination in its application. In the work of purification by exclusion which is thus set before the medical philanthropist, an inquiry will be made into the professional genesis of the self-seekers so graphically described by Dr. Clark. We drop the hint that most of them will be found to have made a short cut from comparative illiteracy to the medical college, having had no rational preliminary education, no proper and sufficient mental discipline.—*The American Lancet.*

In the Treatment of Lithæmia, according to Dr. Da Costa, the main factor is regulation of the diet. The food ought to be mainly vegetable. Green vegetables (especially asparagus), fresh fruits, stale or toasted bread, with the white meat of poultry and fish, should constitute the chief items. An excess of carbo-hydrates, especially sugar, should be avoided. The only drink to be allowed is water, and sufficient quantities should be taken to flush the kidneys. Mineral waters may be ordered to accomplish the same purpose. Alcohol should be positively excluded. Exercise in the open air is also an important part of the treatment. But little drug treatment is required. Saline laxatives are very useful. A combination of lithium carbonate (2 gr.), with extract of nux vomica ($\frac{1}{6}$ gr.), given after meals is of special value. In attacks of lithæmic migraine a few doses of a mineral acid, it is claimed, will often cause the symptoms to disappear. Other authorities advise a diametrically opposite diet to that cited above.

The Relative Value of Man and Horse.—A man in Kentucky while driving was struck by a locomotive and both himself and the horse were killed. The widow sued the railroad company and recovered $50 for the loss of the horse and one cent for that of her husband.

MODIFICATIONS IN THE TECHNIQUE OF VAGINAL HYSTERECTOMY.[1]

BY CLEMENT CLEVELAND, M.D.,

SURGEON TO THE WOMAN'S HOSPITAL, IN THE STATE OF NEW YORK.

IN writing a paper for the Practitioners' Society it is difficult for one engaged in a special branch of work to select a subject for discussion that will be of general interest to its members.

In choosing the present topic, I am aware that it is one with which many of the fellows of the Society are perfectly familiar. The paper, however, is not written for the expert, but for the man who knows little or nothing about the subject, but desires to know more, and the hope is cherished that it will elicit a discussion that will prove of interest and profit to us all. The general practitioner should be not only interested, but familiar with the whole subject of uterine cancer. It is from his early detection of the disease that the best results from the operation are to be expected, for in its promise of cure there is no more beneficent operation in the whole range of gynecological surgery.

In this paper it is my purpose to speak of the operation as applied to cases of cancer alone.

In its anatomy there is nothing more beautiful and admirably adapted for the operation than this organ, in the arrangement and distribution of its arteries, placed as they are where they can be most readily reached without jeopardizing the integrity and function of any other.

The accompanying drawing (Fig. 1) shows the position and distribution of the ovarian and uterine arteries, with their relative position to the ureter. It also shows the proper position of ligatures (A and B) for their control.

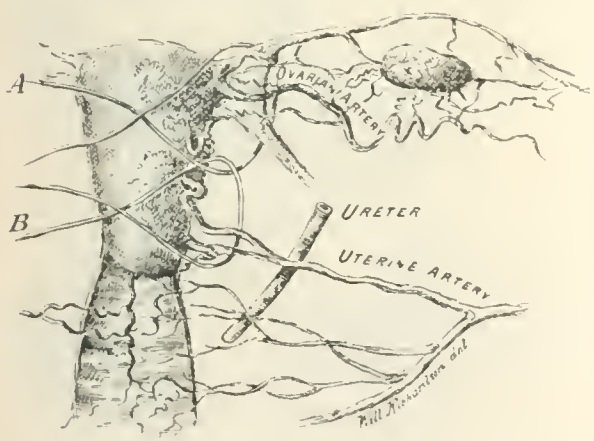

FIG. 1.—Ovarian and Uterine Arteries.

Vaginal hysterectomy, or colpo-hysterectomy, was first performed about fifty years ago, but fell into disfavor from the great mortality following it. To modern antisepsis is due its revival and great popularity.

In cancer of the cervix, so greatly has the mortality been reduced, that but little difference of opinion now exists among gynecologists regarding the question of high amputation or total ablation.

[1] Read before the Practitioners' Society of New York at the meeting held March 2, 1894

Selection of Cases.—A word here about the selection of cases is important, as it bears directly upon the question in hand.

In deciding upon a case the following points should be made out: Bimanual examination, with the patient in the dorsal-decubitus, should discover no extension of disease into the broad ligaments. The uterus should be freely movable. The anterior lip should not be so extensively destroyed that there is no grasp for volsellæ. If the disease has extended to such an extent, the proliferation has probably reached the bladder wall, rendering operative interference worse than useless. The uterus could probably be removed, but a recurrence would be almost immediate. The same is not true of the posterior lip, with extension even upon the posterior wall of the vagina. I have had one case recover from hysterectomy, and live without recurrence for three years, where the posterior lip was almost completely destroyed, and where quite a large section of the posterior wall of the vagina had to be resected.

The uterus should not be too large, not larger than a two and a half months pregnancy. The vagina should be sufficiently capacious. But this I do not look upon as a bar to the operation. If the introitus is too small, the perineum should be incised down even to the sphincter ani. It can be easily sewed up afterward.

I shall take as a typical operation, the one described by Schroeder, and discuss the various modifications, afterward describing the method or combination of methods that I have, from quite an extended experience, found to answer what I consider the requirements of the operation.

Schroeder's method is as follows: The cervix is grasped by volsellæ and pulled down as far as possible, a circular incision is then made, in healthy tissue about the cervix, and the vaginal mucous membrane pushed backward, separating anteriorly the bladder from the cervix. Douglas's pouch is then opened by a transverse incision, and the uterus turned backward, so that the fundus appears in the opening. The fundus is caught with the volsellæ and the body of the uterus pulled through the incision. The peritoneum of the vesico-uterine pouch is then cut through. The broad ligaments are then ligatured either with a single ligature or in separate portions. Finally, the uterus is cut away, close to its sides, leaving sufficient stump to prevent slipping of ligatures.

The wound in the peritoneum is then closed by stitches, securing the stumps of the broad ligaments to the wound, and thus turning them outside. Between both these stumps, he leaves a small opening for a T-shaped drainage-tube, the end of which, protruding from the introitus, is enveloped in salicylated cotton.

Various modifications of these several steps in the operation are practised by prominent gynecologists in this country and in Europe.

Any instrument designed to draw down the uterus by being applied to the cavity, I consider useless. If the cervix is so far destroyed that it affords no grasp for volsellæ or forceps, I believe the operation of hysterectomy is not indicated.

In the first step, instead of using knife or scissors, some advocate the opening of the vaginal pouches by the actual cautery. There is certainly no advantage to be gained by this, and it is objectionable for various reasons. Dissection is made much more difficult thereby, and there is great risk of burning the vulva and vagina.

The application of an elastic ligature to the cervix, be-

fore dissection, as practised by Fritsch, would seem a useless complication. Some follow the method advocated by Fritsch, of beginning the dissection at the sides of the cervix, finding the uterine arteries and tying them. This was adopted evidently to avoid the hemorrhage following the incisions in the vagina about the cervix. The hemorrhage is usually so trifling, and so easily checked, that the supposable gain from the method does not compensate for the loss of time taken in isolating and tying the arteries. For the same reasons I do not advocate the plan followed by Pozzi and others, of suturing the posterior vaginal and peritoneal edges together, and, moreover, I believe by this plan pockets for pus are left. All such surfaces should be kept open to drain.

Instead of opening Douglas's pouch by incision, I believe the peritoneum should be dissected off from the posterior uterine wall by the finger, as far up as it is possible to do so. There is less bleeding, and a larger flap of peritoneum left to close down over the pelvic opening.

I am opposed to retroverting the uterus and drawing the fundus through the opening in Douglas's pouch. It is often a difficult and sometimes an impossible thing to accomplish, owing to the resistance of the round ligaments, and the presence of the cervix anteriorly. I am opposed to any method which is likely to occasion delay, and I have seen so much time lost in attempting to carry out this procedure in the hands of others, that I have never attempted it.

Others besides Schroeder advocate the partial or total closing of the peritoneum. This is not an easy procedure, and takes much time. It interferes with drainage, which I take it, is most important, even from the abdominal cavity, after such an operation. Moreover, within twenty-four hours, nature shuts off the peritoneal cavity by plastic lymph, as thoroughly as suturing would do.

The Use of Clamps.—Clamps of various construction are still used by some for controlling the uterine and ovarian arteries. I believe, however, that within a few years they will be entirely given up. They are objectionable to my mind, for many reasons. Compared with the ligature there is greater risk of hemorrhage, and greater danger of wounding intestines. They increase the danger of sepsis also. I abandoned them myself three years ago, because I lost a case directly due to their use. I had applied four clamps, one to each uterine, and one to each ovarian, artery. It had been my custom to leave the clamps in position for forty eight hours, but in this instance I thought I would be more than usually prudent, and decided to leave them seventy-two, as I got the impression during the operation that the patient was a bleeder. I felt, however, that seventy two hours was long enough, and I began the removal of the clamps at the end of that time. The removal of those from the uterine arteries was accomplished without difficulty or accident, but on attempting to remove the one on the left ovarian artery, as soon as it was cautiously opened, hemorrhage was very free and startling. The clamp was immediately closed again, when all hemorrhage ceased.

Within a few hours the patient began to do badly, and died at the end of forty-eight hours of peritonitis. On the removal of the clamp on the left ovarian artery after death, fecal matter came out through the vaginal opening, thus demonstrating that, when I had reclamped the left ovarian artery, a knuckle of intestine had been caught in the end of the instrument. This was my misfortune, not my fault. It was clearly unavoidable.

Clamps are, moreover, objectionable from the discomfort they give to the patient. Of course very few are needed, but I well remember the first operation of the kind I ever witnessed. There were sixteen clamps in all. But that was in the early days of the operation. It never occurs now at the hands of any expert operator.

I come now to speak of the method which I have found, personally, to best answer the requirements of the operation, as I understand it.

Preparation of the Case.—Where it is possible, it is best to give four or five days, or even a week, to the preparation of the patient. Where it is possible the patient should be given a bath each day, the bowels should be got into condition, so that at the time of the operation the rectum and colon are empty. Vaginal douches should be given twice daily. I have tried nearly everything for this and have settled finally on a solution of bichloride of mercury, 1 to 5,000, as the best cleanser and disinfectant. Several hours before the operation the rectum and sigmoid flexure should be thoroughly washed out, first by soap suds, and then by a saturated solution of boracic acid. After etherization the patient should be placed in the lithotomy position, with legs and thighs

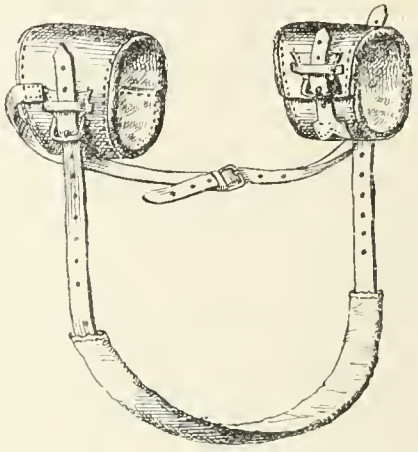

Fig. 2.—The Bissell Crutch.

flexed upon the abdomen and held in place by some form of crutch. I prefer, and use, the one invented by Dr. J. Dougal Bissell, of this city, late house-surgeon of the Woman's Hospital. It is shown in the accompanying diagrams (Figs. 2 and 3). Its chief and important feature is, that it takes its support from the back in the lower lumbar region, instead of from the neck and shoulders. Its advantage over others can be readily seen from this fact. It consists of one strap, broad in its centre part, which is covered by india rubber, with its two tapering ends perforated with the proper number of holes, by which it is attached on either side to two

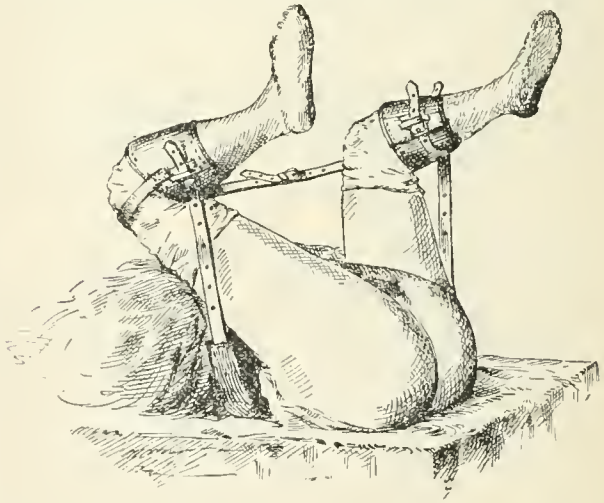

Fig. 3.—The Bissell Crutch Applied.

broad padded leather bands, which fit about the legs just below the knees. There is another strap which is buckled to these same bands between the knees. The diagrams will show the application of the instrument even better than the description (Fig. 3). Another advantage of this crutch is its lightness and the small amount of room it requires when packed for transportation.

The mons is then thoroughly washed with liquid green soap and shaved; the vagina thoroughly washed, also with green soap, and thoroughly irrigated with the 1 to 5,000 bichloride solution.

Where it is at all possible that a laparotomy may be called for as a supplementary measure, the abdomen should be prepared the night before for such an emergency. The legs and abdomen should be thoroughly covered with dry sterilized towels. A large Sims speculum is then introduced and given to a nurse, sitting on the right of the patient, to hold. If necessary retractors can be put in on either side, and held by assistants, or my own bilateral retractor, devised for this purpose, can be used (see Fig. 4). If the introitus is so small that it inter

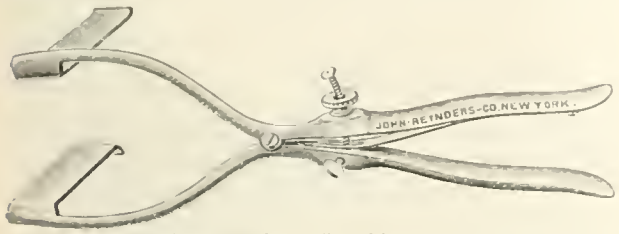

Fig. 4.—Author's Bilateral Retractor.]

feres with the work, I do not hesitate to incise it down to the sphincter ani. The cervix is then grasped by volsellæ and drawn down as far as possible. A block tin sound is passed into the bladder, and the point of connection of the latter with the cervix made out. A transverse incision is then made in healthy tissue below this point, across the anterior lips, and the bladder-wall gradually separated from the cervix, till the unresisting vesico-uterine pouch is reached. A transverse incision is then made across the posterior lip, at the retro-vaginal junction, and the peritoneum pushed backward and upward from the posterior wall as far as it is possible to do so. The incision about the cervix is then made complete by incising the mucous membrane at the sides of the cervix; being careful not to cut deep enough to wound the uterine arteries.

Ligaturing the Uterine Arteries.—In passing ligatures, I use my ligature-carrier, which is here shown in diagram (Fig. 5). With the index finger of the left

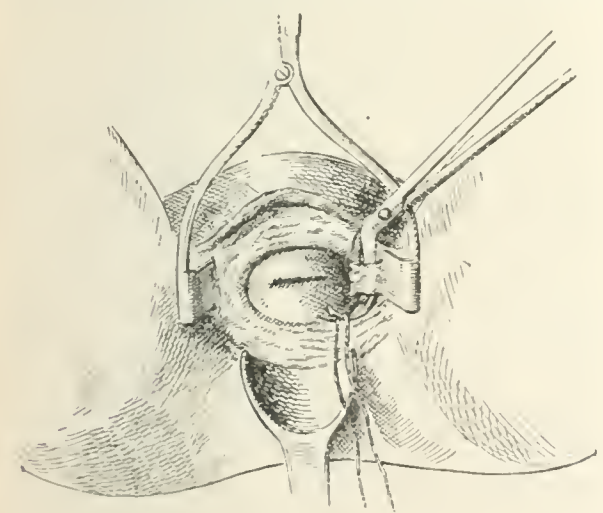

Fig. 5.—Author's Ligature Carrier.

hand passed into the opening in Douglas's pouch, up to the interspace between the ovarian and uterine arteries on the left side, the point of the ligature-passer is carried into the interspace anteriorly and passed at a sufficient distance from the uterus, with the index finger of the left hand in position as a guide, and brought out in the posterior opening, and its jaws opened. The loop of a long double ligature is then placed in the jaws of the ligature-carrier and drawn through. The loop is then cut, and one of the remaining halves is clamped at its upper and lower end. The other half is then used to ligate the left uterine artery. Before doing this I see that these two ligatures are crossed. I do this to secure a chain stitch, believing this the safest guard against hemorrhage. There is thus no space left between the uterine and ovarian ligatures, where serious hemorrhage has been known to occur, when the ligatures were introduced separately.

A double ligature is next introduced in a similar manner on the other side, the loop divided, and one of its halves clamped on its either end as before; the other half is then used in securing the right uterine artery.

The above is shown in the accompanying diagram.

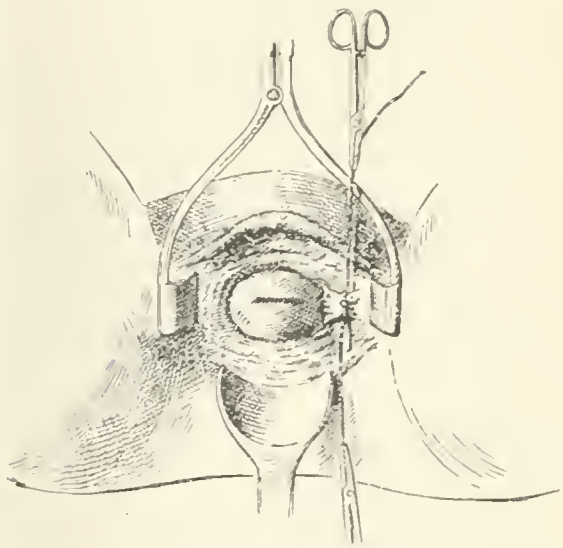

Fig. 6.—A Schematic Drawing.

The cervix is then cut away from the uterine arteries, leaving sufficiently large stumps to avoid slipping of the ligatures.

Thorough and gentle irrigation with saturated solution of boracic acid is then practised. If everything seems secure and there is no hemorrhage, the operation is proceeded with.

The vesico-uterine duplicature of the peritoneum is then penetrated and thoroughly separated from the anterior surface of the uterus, and then the peritoneum is thoroughly separated from the uterus posteriorly as high up as is possible. After gentle and thorough irrigation again with distilled water, under low pressure, the next step is taken up. This consists of the amputation of the cervix. This is done to avoid infecting the peritoneum when the fundus is drawn out, and also to give more room for the easy extraction of the body of the uterus through the anterior opening. I not only amputate the cervix, but with it a large portion of the body of the uterus. This is done with large serrated scissors, which cuts out the cervix, together with a large wedge-shaped portion of the body of the uterus. This is shown in the accompanying diagram (Fig. 7). The incisions

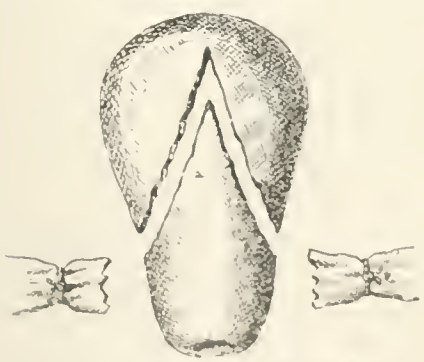

Fig. 7.—Showing Method of Amputating the Cervix.

from either side are often carried to within half an inch of the top of the fundus, where they meet. The fundus is then drawn out by a large hook inserted at its top, great care being taken to avoid the intestines. With the cervix and the large wedged-shaped portion of the body removed, the sides of the uterus come together, and the body is drawn out with great ease. By this method even

very large uteri may be removed. The index finger of the left hand is then introduced in the posterior opening, as a guide for the ligature-carrier, which is then passed in anteriorly over the fundus and out at the posterior opening. The lower end of the previously clamped ligature, on the left side, is then placed in the jaws of the ligature-carrier, and drawn out through the anterior opening. With this ligature the ovarian artery is then secured. A long and delicate clamp is then placed at the top of the broad ligament close to the suture, taking in merely the peritoneum. The uterus is then cut away from the uterine artery, on the left side, leaving a sufficient stump to prevent the slipping of the ligature. The same procedure is gone through with on the other side, and the remainder of the uterus cut away and removed.

These clamps, placed at the top of the broad ligament, are to be used later in the operation for drawing down the stumps of the ovarian arteries sufficiently to secure their being thoroughly covered by the gauze dressing. Before tying the ovarian artery, if I find it advisable, from the size of the uterus, to introduce a third ligature, the ligature carrier is passed anteriorly through the centre of the remaining portion of the broad ligament on the left side, and brought out through the posterior opening, its jaws opened, and the lower end of the previously clamped ligature, together with the end of a third ligature, drawn through.

After seeing that these two ligatures are crossed, the lower one is first tied, and then the other: two ligatures thus taking the place of one. The same is done upon the other side.

For the ligatures I use the medium sized braided Chinese silk. It is the strongest, and can be the most securely tied. These ligatures are all left long and knotted at their ends in such a way as to indicate the arteries to which they are attached, as in the future progress of the case it may be of advantage to know whether they are from the uterine or ovarian arteries; this being important, as they sometimes have to be removed. If left to themselves I have known the ligatures of the ovarian arteries to take six weeks and more before they will come away.

If the ovaries and tubes are non-adherent, and can be readily brought into the opening, I remove them, together with the uterus, by placing them outside of the ligatures of the ovarian arteries, when it is possible to do so. If they are adherent, and not readily brought down, they are left.

I have never yet seen any reason to regret my inability to remove them, though I believe that when the woman has not reached the climacteric it is better that they should be taken away. In such instances their functional activity may keep up disagreeable nervous symptoms.

Gentle and thorough irrigation with very warm distilled water is then practised under low pressure. If there is no hemorrhage, the stump, including the left ovarian artery, is then carefully drawn down a short distance by the clamp attached to it, and a pad, formed of several layers of sterilized iodoform gauze, is packed against the left side of the pelvic opening, covering the stumps of both the ovarian and uterine arteries. While the gauze is held in position, the clamp holding the stump of the uterine artery is gently removed.

In the same manner the stumps of the arteries on the opposite side are covered. The space between these two pads is then packed with strips of sterilized iodoform gauze, down to the introitus. A pad of bichloride gauze is then placed over the vulva, and secured in position by a "T"-bandage. The patient is then ready for bed.

In cases of cancer in the body of the uterus, the first step is to thoroughly curette the uterus, irrigate with strong bichloride solution, and pack the cavity with bichloride gauze; otherwise the technique of the operation does not differ from the one described above.

German Foresight.—During the last seven years the Prussian government has paid over $400,000 indemnity for cattle slaughtered on account of tuberculous disease.

CLINICAL OBSERVATIONS ON EROSIONS OF THE STOMACH AND THEIR TREATMENT.

By MAX EINHORN, M.D.,

NEW YORK.

As is well known, the term "erosion" signifies a defect of superficial nature. In the stomach erosions are often found at the autopsy. Of late several valuable papers on the pathological anatomy of this subject and on the rare occurrence of erosions associated with typical ulcers of the stomach have been published.

In his excellent article, "Ueber geschwürige Processe im Magen," D. Gerhardt[1] describes erosions of the stomach in the following words: "Sections made of erosions as a rule show that at the base of the ulcerations almost the entire lower half of the mucous membrane is still preserved. In the epithelium of these remaining glands nothing remarkable can be discovered; at the sides the glands become longer; the first ones that are intact usually curve themselves over the defect and partly cover it. The recovery seems to take place by the simple aftergrowth of the gland remnants."

Virchow[2] maintains that besides circulatory derangements in the larger vessels of the stomach (art. coron., gastricæ breves, and gastroepiploicæ) the acute and chronic catarrh of the stomach, especially if the latter is accompanied with vomiting and crampy contractions, are the cause of bleeding ulcers and erosions of this organ.

O. Harttung[3] in his article, "Ueber Faltenblutungen und hämorrhagische Erosionen," explains the origin of erosions in the following way: "The contraction of the muscularis of the stomach effects an arrest of the flow in the folds and intense congestion in the veins and capillaries which give cause to hemorrhages into the mucous membrane. . . . An hemorrhagic infiltration of the mucous membrane arises, which, therefore, is only little or not at all provided with fresh circulating blood and very soon succumbs to the digestive effect of the gastric juice. In this way the decay and destruction of the tissue, the hemorrhagic erosion is produced."

Langerhans[4] opposed the commonly accepted view that between erosion and ulcer of the stomach there is only a gradual but no typical difference, and that ulcers of the stomach very frequently originate from the larger erosions. He gave the following reasons: The round ulcer of the stomach has its typical location near the small curvature, and is met with only exceptionally at other places; the hemorrhagic erosions, on the contrary, have no predilection for their seat; the round ulcer appears most frequently as a single ulcer, sometimes as two corresponding ones, but very seldom in greater number; erosions, on the contrary, are met with in large numbers, seldom singly. They are located principally at the tops of the folds of the mucous membrane, and flow together, if they are very numerous and near each other, in the form of elongated and ramified figures corresponding to the folds of the mucous membrane; the round ulcer of the stomach loses its characteristic round shape only if two corresponding ulcers at both sides of the small curvature unite to form one oblong ulcer, the longitudinal diameter of which is always perpendicular to the longitudinal axis of the stomach.

Langerhans believes that primary affections of the vessels (aneurisms, embolics, etc.) are but very seldom the cause of hemorrhagic erosions, and that, on the other hand, catarrhal inflammations, with crampy contractions of the muscularis, but exceptionally cause the formation of chronic corrosive ulcers. Ordinarily hemorrhagic erosions appear in crampy contractions accompanied with inflammatory processes, round ulcers of the stomach in primary affections of an arterial vessel. Only very exceptionally do erosions become transformed into chronic ulcers.

[1] D. Gerhardt: Virchow Arch., Bd. 127, p. 85.
[2] R. Virchow: Virchow Arch., Bd. v., p. 363.
[3] O. Harttung: Deutsche med. Wochenschr., 1890, No. 38, p. 847.
[4] R. Langerhans: Virchow Arch., Bd. 124, p. 373.

Such exceptional cases in which gastric ulcers very probably took their origin from erosions are described by Langerhans and Gerhardt in their previously mentioned papers.

Ewald,[1] speaking of the etiology of ulcus rotundum ventriculi, mentions also erosions as an important factor, and describes the microscopic picture of a stomach which has been treated according to Heidenhain's method shortly after death. The mucous membrane of this stomach was suffused with blood, and at different places the glandular tubules were filled to beyond their necks with unmistakable red blood-corpuscles. "A very slight local congestion or a traumatism," Ewald remarks at this place, "may be the cause of such bleedings. They develop into the hemorrhagic erosions, small, streak-like, or rounded losses of substance from the size of a millet-seed to that of a pea, on which at times a blackish-brown extravasation of blood is found, together with the simultaneous loosening of the mucous membrane. Their number is very variable, being sometimes enormous, especially near the pylorus, so that the stomach appears as if covered with them."

Whereas the subject in question has been thoroughly discussed and worked at in respect to the pathological anatomy in the aforementioned literature, very little has been done clinically. Although erosions of the mucous membranes of the stomach are mentioned in some text-books, there is nowhere defined how these conditions may be recognized during life.

The only papers which in a slight measure touch the clinical side of this subject are the following:

Jaworski and Korczynski[2] describe non dangerous exfoliations of the gastric mucous membrane with traces of bleeding of the stomach caused by the tube; unless they originate from an artificially ruptured ulcer or cancer, they are never large, and confine themselves to the red coloration of a few portions of mucous membrane, and at the utmost to pink tinging of the washed stomach contents. These small artificial bleedings are different from other hemorrhages of the stomach; they are fresh and show under the microscope unchanged red blood corpuscles which are dissipated in the parenchyma of the mucous membrane. These artificial bleedings occur principally in patients suffering from chronic gastric catarrh (lack of HCl secretion), thus frequently in carcinomatous stomachs.

Boas[3] says, in his book on "Diseases of the Stomach:" "Sometimes when fasting there appears in the stomach contents also desquamated epithelium and remnants of glandular tubes. They are found oftener than could be concluded from the description given by other authors. In several instances I have observed clear fragments of glandular tubes which could be recognized with certainty." Boas also mentions the occurrence of small exfoliations of the mucous membrane. He speaks of them, however, as something accidental, which could be utilized for the diagnosis by microscopic examination.

Contrary to these described accidental occurrences of pieces of gastric mucous membrane, I have observed during the last two years seven patients in whom the presence of particles of the gastric mucous membrane in the washwater of the stomach was quite the rule. These cases resemble each other in so many respects that they appear as if belonging to one sickness. They could best be considered as erosions of the gastric mucous membrane. It might be appropriate at first to describe these cases as they have been observed clinically, and thereafter to discuss the type of the disease.

Case I.—June, 1892. M. S——, thirty-four years of age, shoemaker, is for the last four years troubled with pains after meals. As a rule, the pains are not severe; sometimes, however, although quite seldom, they appear with intensity. Patient feels extremely weak and languid. Appetite ordinarily very poor, bowels constipated.

[1] C. A. Ewald: Diseases of the Stomach, p. 236, 1892.

[2] Jaworski and Korczynski: Deutsche med. Wochenschrift, 1886, No. 49, p. 875.

[3] Boas: Allgemeine Diagnostik und Therapie der Magenkrankheiten, p. 171. Leipzig, 1890.

Status præsens: Strongly built man; mucous membranes well colored; cheeks hollow. Chest organs intact. Stomach not enlarged, sensitive to pressure, but not specially painful.

The examination of the stomach contents one hour after Ewald's test-breakfast, which has been repeatedly done, always showed absence of the free hydrochloric acid, presence of small quantities of combined HCl and ferments; not much mucus.

June 3.—When fasting: stomach empty; lavage: in the wash water there are found three red pieces of mucous membrane. (One small piece is examined in glycerin under the microscope and well-preserved glands found.) The stomach is sprayed with a one per mille silver nitrate solution.

June 5th.—Lavage: three red pieces of mucous membrane appear in the wash-water. Spray with argent. nitr.

June 7th.—Lavage: two red pieces of mucous membrane. Spray with argent. nitr.

June 10th.—Patient feels better. Lavage: no pieces of mucous membrane. Spray with argent. nitr.

June 13th.—Lavage: no pieces of mucous membrane. Spray with argent. nitr.

June 16th.—Lavage: no pieces of mucous membrane. Spray with argent. nitr.

The treatment is discontinued. Patient feels well almost a whole year, and lives without any complaints whatever. On July 4, 1893, patient consulted me anew. He asserted that he was troubled with poor appetite, pains after meals, and extreme weakness for the last three to four weeks.

When fasting: stomach empty; lavage: two red pieces of mucous membrane are found in the wash-water; one of them being 1 ctm. long and 0.5 ctm. wide. Spray with argent. nitr.

July 6th.—Lavage: two red pieces of mucous membrane appear in the wash-water. Spray with argent. nitr.

July 8th.—Patient feels considerably better. Lavage: one red piece of mucous membrane. Spray with argent. nitr.

July 11th.—Lavage: no mucous membrane. Spray with argent. nitr.

July 14 and 17, 1893.—The same condition is noticed during lavage (*i.e.*, no pieces of mucous membrane appear), and the stomach sprayed with argent. nitr. Patient is dispensed from treatment.

Case II.—January 12, 1893. M. G——, aged thirty, merchant, had influenza three years ago. Since that time patient began to suffer from digestive troubles: he used to vomit immediately after meals; patient once noticed in the vomited matter some thick, light, red blood, mixed with mucus (the quantity was one small liquor glass). Patient is troubled, besides, with pains in his back for ten years; these pains increased after the grippe. Poor appetite, no relish of food. Bowels always good. Patient is not much emaciated.

Status præsens: The chest organs do not show anything abnormal. The stomach reaches until about one finger's width above the navel. The gastric region is painful to pressure. The diagnosis was made probable ulcer of the stomach, and the patient subjected to the ordinary rest-treatment. Patient has been fed exclusively per rectum during the first week, and thereupon ordered a milk-diet for two weeks. During all this time warm flaxseed poultices have been applied. During this treatment, and also for some time thereafter, the vomiting stopped, and the pains were less severe when they appeared. Soon, however, patient began to complain anew, and by the middle of February, 1893, all the old symptoms had reappeared.

February 25.—When fasting: the stomach is washed out (during the lavage of this morning as well as in almost all the following washings, more or less violent coughing and sometimes nausea spells appear). In the wash-water four pieces of mucous membrane (bloody red) are found. Spray with a one per mille nitrate of silver solution.

February 27th.—When fasting, lavage (during this procedure vehement coughing spell): in the wash-water four red pieces of mucous membrane are found; the wash-water has a slightly pink color (admixture of traces of blood). Spray with argent. nitr.

March 1st.—Lavage: in the wash-water four red pieces of mucous membrane: the water is slightly red, especially the last part of it (admixture of blood). Spray with argent. nitr.

March 3d.—Intra gastric galvanization.

March 5th.—Lavage: several pieces of blood-red mucous membrane. Spray with argent. nitr.

March 7th.—Patient feels better. The stomach is sprayed with argent. nitr.

March 9th.—When fasting, lavage: no pieces of mucous membrane; the wash-water, however, is a trace red. Spray with argent. nitr.

March 11th.—Spray with argent. nitr.

March 13th.—Lavage: one red piece of mucous membrane. Spray with argent. nitr.

March 15th.—Spray with argent. nitr.

March 17th.—Lavage: no pieces of mucous membrane in the wash water.

March 19th.—Examination of the stomach contents one hour after Ewald's test-breakfast: HCl = 0; acidity = 4; no lactic acid; rennet ferment = 0; rennet zymogen +.

March 22d.—Spray with argent. nitr.

March 25th.—Patient complains of having more pains. Lavage: three red pieces of mucous membrane; in taking out the tube, some blood-red water appears. Spray with argent. nitr.

FIG. 1.—A piece of gastric mucosa (patient M. G——), showing the glands mostly vertically cut, and accumulations of red blood-corpuscles on the lower right-hand corner.

March 27th.—Spray with an ichthyol solution.

March 29th.—Spray with an ichthyol solution.

March 31st.—Patient does not feel any better. Lavage: several red colored pieces of mucous membrane. Spray with one per cent. alumnol solution.

April 2d and 4th.—Spray with alumnol.

April 6th.—Lavage; only one red piece of mucous membrane. In taking out the tube some bloody water appears. Spray with alumnol.

April 8th.—Spray with alumnol. As the patient did not improve by the local treatment, the same is for the present discontinued. The patient was given arsenic and iron for some time; his condition, however, did not seem to be influenced by these medicaments.

Besides the pieces of gastric mucous membrane, the wash-water (especially the last part which was emptied when taking out the tube) showed a slight red color. This gave ground to the supposition that the sore spots may be situated at the small curvature, probably not very distant from the cardia. As the patient offered a grave condition (inability to walk, extreme weariness, pains in the gastric region as well as principally in the back in the neighborhood of the seventh vertebra), it appeared to me (and also to one of the best surgeons of this city) that an operation (exploratory laparotomy), with the intention of an eventual excision of the erosions (if there should be only few of them) would possibly give some benefit.

The patient left for Germany and consulted several colleagues, but none advised an operation; he was sent to Kissingen, where he passed six weeks without any benefit, and finally returned to New York with his old complaints.

The examination of the patient on January 6, 1894, showed the conditions unchanged: When fasting, lavage: three red pieces of mucous membrane appear in the wash-water; one of the pieces is 1 ctm. long and 0.4 ctm. wide, and shows several dark red ecchymoses of the size of the head of a pin; several microscopic specimens have been prepared, some in the fresh condition the others dried and stained; one can easily see the glandular tubes and certain places of group-wise accumulations of red blood-corpuscles (see Fig. 1); this latter being of a slightly red color.

CASE III.—February 11, 1893.—H. S——, aged thirty-five, merchant, suffers for two to three years from digestive troubles. These consist principally in the appearance of pains right after meals; the pains are not severe; they produce, however, the effect that patient eats less. There is a feeling of fulness; bowels constipated. Patient always feels weak and tired.

The examination reveals: chest organs intact; the gastric region is sensitive to pressure; there is splashing sound extending two fingers'-width below the navel; right kidney movable.

The examination of the stomach contents one hour after Ewald's test-breakfast showed: HCl +; acidity = 60.

February 13th.—When fasting: stomach empty. Lavage: in the wash-water three small red pieces of mucous membrane are found. Spray with argent. nitr.

February 14th.—Intra gastric galvanization.

February 15th.—Lavage: in the wash-water three small red pieces of mucous membrane appear. A fresh microscopic specimen shows gastric glands. Spray with argent. nitr.

February 16th.—Patient feels better—*i.e.*, he is stronger, can eat more, and is not troubled with pains. Direct galvanization of the stomach.

February 17th.—Lavage: no pieces of mucous membrane are found. Spray with argent. nitr.

February 18th.—Intra gastric galvanization.

February 19th.—Lavage: no pieces of mucous membrane. Spray with argent. nitr.

February 20th.—Intra-gastric galvanization.

February 21st.—Examination of the stomach contents one hour after the test-breakfast: HCl +; acidity = 54; no pieces of mucous membrane.

February 22d.—Direct galvanization of the stomach.

February 23d.—Lavage: no pieces of mucous membrane. Spray with argent. nitr.

February 24th.—Intra gastric galvanization. Patient had to return to his native city, Chicago, on account of urgent business. As I have recently heard, patient tient felt well all the time with but few intervals.

CASE IV.—April 24, 1893. L. A——, aged thirty-three, merchant, suffered for two to three years from temporary attacks of pains right after meals. The pains are not of a severe nature; they, however, have a depressing effect on patient and cause him to partake of much less food than he is otherwise used to. The bowels are only slightly costive. The periods of pains extend over about two to three months and are then followed by periods of complete euphoria. For a month the patient has pains after meals; the appetite is poor, and frequently a feeling of extreme weakness overcomes the patient.

Status præsens: Chest organs do not reveal anything abnormal. The gastric region is sensitive to pressure, but there is no distinct pain. After the partaking of half a glassful of water, a splashing sound can be produced extending to two fingers'-width above the navel.

April 27th.—The stomach contents are examined one hour after the test-breakfast: HCl +; acidity = 30.

Patient was given nux vomica and gastro faradized three times, but without showing any improvement.

May 9th.—When fasting, lavage: four red pieces of gastric mucous membrane appear in the wash water. Spray with a one per mille nitrate of silver solution.

May 11th.—When fasting, lavage: four red pieces of mucous membrane are found in the wash water. Spray with argent. nitr.

May 13th.—Intra gastric galvanization.

May 15th.—When fasting, lavage: one piece of mucous membrane is found in the wash-water. Spray with argent. nitr.

May 17th.—Intra-gastric galvanization.

May 19th.—When fasting, lavage: no pieces of mucous membrane in the wash water. Patient feels much better and leaves for the country.

Case V.—April 19, 1893.—B. M. S——, aged twenty-six, merchant, complains for two and a half years of digestive troubles. At first patient had lack of appetite, pains after meals, and nausea, but no vomiting. Feeling of weariness and fatigue; constipation. After some continued treatment and a trip to the South the condition of the patient improved for a while; soon, however, it got worse again. During the last two years patient has constantly pains right after meals, with but very few exceptions, and feels very weak. When fasting, patient, as a rule, feels well.

Status præsens: Chest organs intact; the gastric region is sensitive to pressure. After drinking half a glassful of water a splashing sound can be produced, extending to one to two fingers'-width above the navel. Liver not enlarged. Urine contains neither sugar nor albumin.

April 20th.—Examination of the stomach contents one hour after Ewald's test-breakfast shows: HCl +; acidity = 60; admixture of much mucus.

Diagnosis: Gastritis gland. chron. mucosa.

April 21st.—When fasting, stomach empty, lavage: in the wash water, three red pieces of gastric mucous membrane. (A fresh specimen in glycerine shows gastric glands.) Spray with arg. nit.

April 23d.—Intra gastric galvanization.

April 25th.—Lavage: three red pieces of mucous membrane appear in the wash water. Spray with argent. nitr.

April 27th and 29th.—Direct galvanization of the stomach. Patient had to leave New York on account of business and returned on May 17th.

May 18th.—When fasting, stomach empty, lavage: three red pieces of mucous membrane are found in the wash-water. Spray with argent. nitr.

May 20th.—Intra gastric galvanization.

May 22d.—Lavage: two red pieces of mucous membrane are found. Spray with arg. nitr.

May 24th.—Patient feels better, has a better appetite, and hardly any pain. Lavage: no pieces of mucous membrane are found. Spray with argent. nitr.

May 26th.—Direct galvanization of the stomach.

May 30th.—Lavage: no pieces of mucous membrane. Spray with argent. nitr.

June 2.—Intra-gastric galvanization. Patient feels well and is, therefore, for the present dismissed.

Case VI.—August 24, 1893.—G. B——, aged thirty-two, merchant, complains for about ten years from digestive troubles. Appetite is seldom good; after meals patient has a slight painful feeling in the gastric region. Bowels almost always constipated. Off and on there appears a feeling of extreme fatigue to such a degree that patient is hardly able to walk. There was never vomiting, but very frequently much belching. Flat taste in the mouth, and, at times, highly increased salivation. Patient has been in Carlsbad several times, but without any benefit.

Status præsens: Chest organs intact. The gastric region sensitive to pressure, but not considerably painful. Splashing sound after the partaking of half a glassful of water extending to three fingers'-width above the navel.

August 26th.—The examination of the stomach contents one hour after Ewald's test breakfast shows: HCl = 0; acidity = 24; Rennet ferment +; very much viscid mucous.

Diagnosis: Gastritis gland. chron. mucosa.

Treatment: Strychnia and iron; besides extr. fluid. Cascar. sagrad.

Patient then left for his native city, Altoona, but returned to New York at the beginning of November, in order to undergo treatment.

November 2d.—When fasting, stomach empty, lavage: in the wash-water, much mucus and two red pieces of gastric mucosa. Spray with argent. nitr.

November 4th.—Direct galvanization of the stomach.

November 6th.—Lavage: two red pieces of mucous membrane. Spray with argent. nitr.

November 8th.—Patient feels better; he can eat more and feels stronger. The examination of the stomach contents one hour after the test-breakfast shows: HCl +; acidity = 52.

November 11th.—Direct galvanization of the stomach.

November 14th.—Lavage: no pieces of mucous membrane found. Spray with argent. nitr.

November 17th.—Intra gastric galvanization.

November 19th.—Lavage: no pieces of mucous membrane. Spray with argent. nitr.

November 22d.—Direct galvanization of the stomach.

November 24th.—Lavage: no pieces of mucous membrane. Spray with argent. nitr.

November 26th.—Intra-gastric galvanization.

Patient feels better and returns home.

Case VII.—May 20, 1893. J. J. M——, thirty-six years of age, pharmacist, began to suffer from digestive troubles five years ago. Appetite was very poor. Patient ate only, as he expressed himself, "from habit." Tongue thickly coated. Frequently dizziness and darkness in front of the eyes. This latter symptom often appeared so violently that the patient had to stop work for fifteen to twenty minutes, in order to recuperate. Fatigue and general weakness. Bowels always constipated. Feeling of pressure in the gastric region, only seldom increasing after meals.

Besides these general symptoms, patient two to three times yearly had attacks growing worse. These attacks were as follows: at night patient fell asleep with the feeling of extreme fatigue; at 2 A.M. he used to wake up with a strong irritation in the throat and in the œsophagus and spat constantly thick mucus. This condition (*i.e.*, the uninterrupted spitting) used to last frequently until 4 A.M or 4.30 A.M., and patient nearly always was obliged to provoke vomiting by tickling his throat in order to get relief. These attacks of deterioration used to last three to six weeks. During such an attack patient came under my care.

Status præsens: Slender man with very thin panniculus adiposus; cheeks somewhat hollow. Chest organs intact. The gastric region is somewhat sensitive to pressure, but no intense pain can be produced at any place. There is a splashing sound extending to one to two finger's-width above the navel. Tongue heavily coated. Knee-jerk present, perhaps somewhat increased. Patient can stand with eyes closed. Urine does not contain any sugar nor albumin.

The examination of the stomach contents on May 21st, one hour after Ewald's test-breakfast, showed: HCl +; acidity = 96; lactic acid not present.

Diagnosis: hyperacidity. Treatment: alkalies; richly albuminous diet.

May 23d.—When fasting, stomach empty, lavage: in the wash-water three red pieces of gastric mucosa are found. Spray with one per mille nitrate of silver solution.

May 25th.—Intra gastric galvanization.

May 27th.—Lavage: in the wash water two red pieces of mucous membrane. (One small piece examined under the microscope in the fresh state shows gastric glands.) Spray with argent. nitr.

May 29th.—Direct galvanization of the stomach.

May 31st.—Lavage: no pieces of mucous membrane are found. Spray with argent. nitr.

June 2d.—Direct galvanization of the stomach. Patient has a good appetite and feels much stronger. The feeling of pressure has disappeared and sleep is good. Further treatment is therefore dispensed with.

In summing up all the cases described one is confronted with the following striking points: In washing the stomach when the patient is in the fasting condition 1 to 4 small pieces of gastric mucous membrane are found. They are about 0.3 to 0.4 ctm. long and nearly as wide, and present a blood-red color. Under the microscope one sees well-preserved glands and accumulations of red blood corpuscles. These pieces of gastric mucosa are constantly found if the stomach of the patient is washed out in the fasting condition. We have not to deal here with an incidental lesion caused by the tube, for, on the one hand, the lavage has been performed without any aspiration and by means of a soft tube; on the other hand, one could not observe in a casual lesion that constancy which is found here.

Besides this objective point in the patients mentioned, several subjective symptoms appear with particular clearness, namely: pains, emaciation, feeling of weakness.

The pains, as a rule, are not intense, and make their appearance right after meals, no matter what has been eaten. They last various lengths of time (one to two hours), and then gradually disappear. Complaints of severe attacks of pains we have never met with in these cases. Frequently there appear, for periods of different lengths, intervals perfectly free from pains, combined with a feeling of complete euphoria. Only seldom do the patients feel pains all the time without reference to food.

Emaciation.—Most cases observed lost in flesh during the first period of their sickness, but thereafter kept up their weight quite constantly. They looked rather thin (in the face the jaws protrude, the cheeks are thin and somewhat hollow), but did not, however, present that cachectic color we are accustomed to meet in carcinoma and other grave chronic troubles.

Feeling of Weakness.—All the patients complained of a feeling of lassitude, weakness, lack of ambition, and in ability to work, and of a decrease of bodily strength. This symptom appears most markedly right after meals, and decreases somewhat a little while afterward (one-half to one hour). In one of my patients (G. B——) there usually appeared, once in a week or in a fortnight, an acme of this symptom, associated with complete anorexia, and lasted for about two days. During this period of deterioration patient was hardly able to walk.

What is the Condition of the Gastric Juice in the Cases Described?—In the first six, one encounters a decrease in the HCl secretion and in the acidity of the stomach contents. In two of these cases (G. B—— and B. M. S——), there was always found a considerable amount of mucus. In all these cases the diagnosis has been made: "Gastritis gland. chronica," in the two last, "Gastritis gland. chron. mucosa." In the seventh case (J. J. M——), however, there was found superacidity caused by an increased HCl secretion.

How are We to Explain the Constant Occurrence of the Small Pieces of Gastric Mucosa?—In six of the cases narrated blood was never found in the wash water carrying the small pieces of mucous membrane. Only in one patient (M. G——), the wash water often used to have a very slight red color. In this case coughing spells frequently appeared during lavage, and in such an instance, besides the pieces of gastric mucosa, the water was stained slightly red.

The pieces of gastric mucosa found in the wash-water of our patients probably must have partly or wholly peeled off from the mucous membrane of the stomach some time previous to the washing. This would explain why there is no bleeding during the lavage. The spots on which the exfoliations have taken place and thus present "erosions," might explain the soreness met with in our patients. One can also easily understand the appearance of blood from the sore spots caused by violent contractions of the stomach during a coughing spell (in case M. G——).

It is very difficult, or perhaps at present hardly possible to decide, whether the exfoliations always take place at the same spots—the mucous membrane constantly becoming replaced and peeled off again—or whether the whole (or a great part) of the inner surface of the stomach is affected in such a manner that small pieces of mucosa easily peel off here and there. This question can only be answered after a long study of vast clinical and pathologico anatomical material. These exfoliations take place (whether always on the same or on different spots) day by day in the stomach of our patients, and effect temporary erosions.

In all cases mentioned, similar in so many points, one constantly encounters the exfoliations of the gastric mucosa, respectively the resulting erosions. Therefore this pathological condition might be most suitably termed "Erosions of the stomach." [1]

Etiology.—In the greatest number of cases mentioned there was found chronic gastric catarrh associated with erosions. The same probably gave cause to the origin of the latter anomaly. Some cases of erosions of the stomach may, however, be caused by some factors yet unknown.

Course.—The course of this pathological condition is a very prolonged one. Several of the patients appear to have suffered from it for many years. Although there may be intervals of perfect euphoria (at the same time

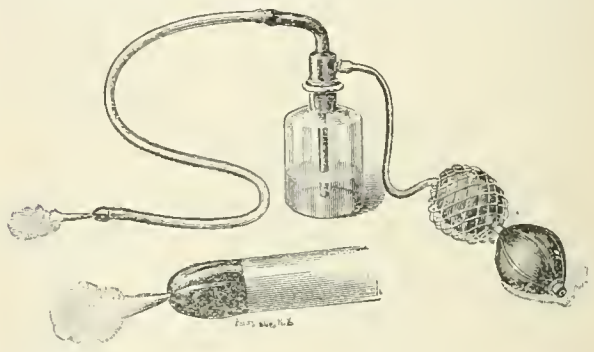

Fig. 2.—Gastric Spray Apparatus.

probably the inner layer of the stomach is completely intact) for a longer or shorter period of time, the old symptoms do, however, sooner or later return.

One would imagine that cases of erosions of the stomach would present a very fruitful soil for the development of ulcers. This, however, does not seem to be the case. For in none of the patients (with the only exception perhaps of M. G——), was there any justifiable supposition of an existing ulcer during the long course of the sickness.

Treatment.—The local treatment of the stomach here plays a great rôle. The astringent effect of nitrate of silver solutions in similar more accessible affections led me to apply this substance directly to the inside of the stomach. This can best be achieved by means of the spray. It was on this occasion that I constructed the gastric spray apparatus (see Fig. 2), and recommended its use in the field of diseases of the stomach.[2]

The treatment is given in the following way: First, the stomach in a fasting condition is washed out with lukewarm water; when all the water has been emptied, the tube is removed from the stomach. The spray apparatus is filled with 10 c.c. of a 1 to 2 per mille solution of nitrate of silver, the tube end dipped into warm water and inserted into the stomach (length of tubing 50 ctm.); thereupon the whole, or at least the greater part of the solution in the bottle is sprayed; the bottle is then opened and the spray-tube removed from the stomach.

In fact the good result of this method of treatment can frequently be best shown in the affection in question.

[1] Remark.—We prefer the term "Erosions of the stomach" instead of the more correct but longer name, "Erosions of the gastric mucosa," as there is no fear of any misunderstanding.

[2] M. Einhorn: New York Medical Journal, September, 1892.

For after the spraying has been done several times the small pieces of gastric mucosa cease to appear. Associated with the objective symptom there appears an amelioration in the subjective feeling of the patient; the pains grow considerably less or entirely disappear, and the strength increases.

I usually combine the spray-nitrate of silver treatment with intra-gastric galvanization; alternately applying the spray or the galvanization. The reason for the use of galvanization in these cases lies in the fact that I had such effective results in two other cases of probable erosions of the stomach, complicated with heart trouble,[1] by means of galvanization alone. The methodical application of intra-gastric galvanization combined with the spray seems to increase the curative effect.

As to diet, there is no need for being very rigorous in these cases. Frequent meals, avoiding heavy vegetables, salads, and pastries, is all I ordinarily require.

Cold ablutions, light gymnastics, out-door life are to be warmly recommended.

Of medicaments condurango and nux vomica are frequently, and a good, easily assimilated iron preparation always, appropriate.

Although these medicaments may be of value as adjuvants, we should rely, in my opinion, mainly upon the local treatment.

107 East Sixty-fifth Street.

THE INTERMITTENT RAPID DILATATION OF URETHRAL STRICTURE.

By OTIS K. NEWELL, M.D.,

SURGEON TO OUT-PATIENT DEPARTMENT OF THE MASSACHUSETTS GENERAL HOSPITAL, BOSTON.

With the multiplicity of modern medical communications it is essential to be as brief as possible in the presentation of any matter which we may deem worthy of professional attention. I shall, therefore, as concisely as possible, describe what I consider to be an improved method of treating such urethral strictures as come within a class to be later described.

However much or little interest one may take in the treatment of urethral stricture, it is certainly a serious disease if allowed to progress neglected to its harmful late effects, and one which every surgeon meets in large numbers and to which in polyclinic, hospital, and private practice, he must devote much valuable time. It would be well, therefore, if possible, to have a uniform method of treatment. Under the present exact conditions of surgery, where all sorts of instruments can be sterilized and bladders and urethræ so successfully disinfected, I imagine that a fairer and more scientific comparison of methods will soon bring this desired result about.

First, I think it is fair to claim, and I certainly do so as far as my knowledge and experience go, that true organic urethral stricture, like œsophageal and rectal, is an incurable condition, except possibly by plastic operation, and one which if neglected will sooner or later return to its original or even a worse condition. It is at the same time more easily controlled under proper management than any of the others.

Now, as to the treatment of stricture, I think most surgeons will to-day agree that the best is gradual dilatation through the introduction of metallic sounds wherever progress can so be made. I have never seen a case where sufficient stretching could not be always thus accomplished, wheresoever the stricture might be situated, provided a beginning could be made with a metallic instrument of sufficient calibre to admit of safe manipulation. In following this practice I feel safe in the precedents established by Syme, Liston, Phillips, and others and a personal observation, during twelve years, of cases so treated at the Massachusetts General Hospital by Drs. Bigelow, Hodges, and Beach, during my connection at the hospital as an interne and surgeon to out-patients. But it should not be for a moment in any way overlooked that in the very tough fibrous penile strictures progress in this way is and should be very slow. They have usually been of slow formation, or if not have become very rapidly organized and intensely cicatricial. To stretch and cause them to absorb as much as possible, therefore, the process should be a slow one. I never consider the treatment completed until the patient possesses a steel sound and can pass it readily, and is taught that he must, as long as he lives, do so at varying intervals according to the tendency to recontraction. Of course a vast number of what we call strictures belong to the little organized class, dilate readily and rapidly, perhaps even in one or two sittings, and do not recur during the remainder of life as far as any symptoms calling attention to them give evidence. Now in the very fibrous penile strictures, I have simply found it necessary in a few instances to prescribe for the patient, somewhat early in the treatment, a smaller sound than you wish him eventually to use. With this passed twice a week, or even every other day, by himself, some absorption and the stretching are readily brought about, and he soon finds himself able to pass a larger size and reach eventually the desired degree of stretching. Thus if the surgeon cannot, from lack of time on his part, or want of either means or time on that of the patient, dilate further than 18 to 24 F., the patient may continue as indicated above to the desired calibre.

All other strictures than the above class are either impermeable, or those where from smallness of calibre practically no progress can be made by gradual dilatation. As to the impermeable ones I think all surgeons agree that the best treatment for them is external urethrotomy. In fact there is practically no other choice left to us if the stricture really is impermeable.

For the remaining class I wish to offer a method which I have found very successful and satisfactory both to the patient and surgeon, but particularly to the patient, as it generally does not necessitate his interruption of work by any period spent in bed. The exceptions being cases where from very poor physique or condition of urine it is wiser to have some rest in bed. I have as yet met with only one such case, and that was where I recommended the patient to the hospital, because he was without proper home attendance, and suffering at the first visit from pain, hæmaturia, and partial retention. I relieved the partial retention, however, one week before his entrance to the hospital, by passing the then first size, No. 14 F., of my improved dilator. This dilator is similar in construction to that described by me in this journal of June 6, 1891; but has the important addition, for this method, of other dilatating or stretching staffs descending in size to 10 F., the latter being not much larger in calibre than the original metallic guide of 8 F. which is of course introduced first, or follows when necessary the small capillary bougie guide to which it may be screwed.

To illustrate what I have called intermittent rapid dilatation let us take an extreme case and describe the method. We will suppose a patient comes passing his urine in the finest possible stream or even by drops; that after a week or more of trial we fail to introduce the finest capillary guide. Our patient finally sends for us, with retention, and we are called upon to do the best possible thing for him. Under ether or local anæsthesia, and preferably local anæsthesia, we finally introduce the capillary bougie guide and eliminate his case from the impermeable class. Now, however, why should we, just because this man has retention, commit him, as has been previously done, to a violent and serious operation by a full divulsion of a perineal section? From no necessity, I believe.

The able review of the operation of divulsion by Dr. Scudder, of Boston,[1] in a study of four hundred and four cases so operated upon at the Massachusetts General Hospital, shows the operation in uncomplicated cases to have practically no mortality. This low mortality, one and nine-tenths per cent., in such a large series of unse-

[1] Max Einhorn: New York Medical Journal, July 8, 1893.

[1] Journal of Cutaneous and Genito-Urinary Diseases, October, 1893.

lected cases treated by six different surgeons and including in the fatal ones complications of serious organic disease, as Dr. Scudder so clearly shows by his careful analysis, is one of the strongest arguments that can be offered in support of divulsion. But again the striking

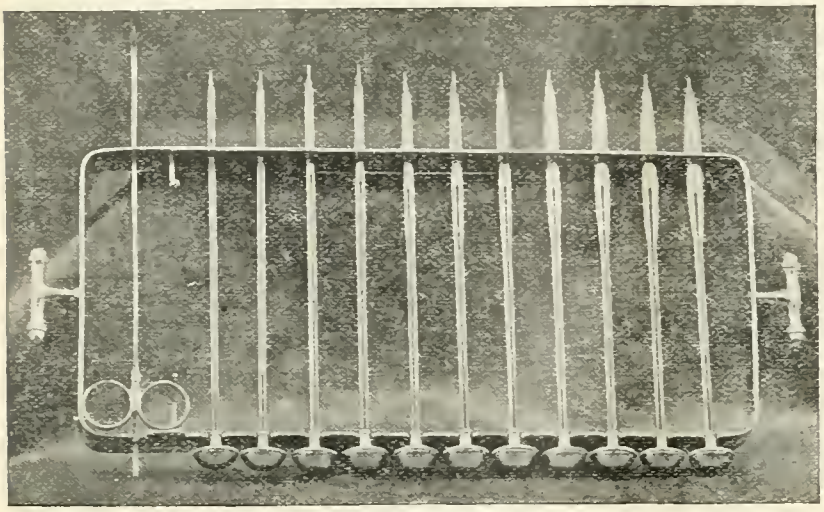

Fig. 1.—Dilating Staffs.

fact is shown that these cases spent anywhere from six to thirty days in bed, with an average of twelve days of confinement to the bed, some with and some without permanent catheter drainage.

The reason why full divulsion has been done in the past, I think, is because, unlike œsophageal or rectal stricture, where small quantities of what must pass through the stricture to maintain life might be several days in so doing, the urethral stricture, when developed to the point of retention, controls the outlet of an organ, the contents of which must as a rule be voided in each twenty-four hours, or else give rise to a dangerous emergency. With the guide to our dilator introduced, it is only necessary to pass down upon it the first few sizes of our dilating staffs, say up to 14 and 16 F. or even 18 F. The retention is at once relieved, a small stream is readily passed, and in two or three days, sometimes even on the next, the patient is able to have one or more larger sizes passed, and so on without any trouble up to the point where the further gradual dilatation with larger sounds is readily accomplished. Of course, where there is no

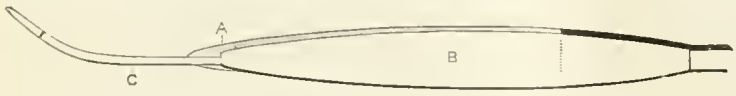

Fig. 3.—Split Guiding Staff. *C*, split guide; *A*, central blade; *B*, dilating staff.

retention and the small flexible or stiff guide can be at once introduced, this method is still more easily adopted.

Another great advantage which I find in my dilator is that, by passing the dilating staff always through the stricture on the guide which is first introduced, the operation is made a mechanically certain one, and such accidents as making a false passage, forcing in a sound when it is engaged in one instead of the urethra, or carrying in and invaginating a portion of the passage, are made impossible. This is especially true when working with instruments below 24 F. in calibre. Doing whatever stretching we deem wise at any particular stage of the treatment with the guiding staff always first passed into the bladder, we eliminate at once all trouble or doubt as to where a free and unguided sound may be going, or what it may be going to do, and thus limit our responsibility to the amount of stretching which is at each sitting deemed judicious. Does this not seem reasonable? Would anything but dire necessity induce us to violently tear open an œsophageal or rectal stricture which had gradually contracted to a lumen of minute size?

This method I have previously suggested in the article above referred to, by what I then called preparatory divulsion. Thus further developed it has proved still more satisfactory, and I therefore earnestly recommend it to professional attention and trial. I claim it to be a rational and mechanically certain procedure, in the greatest degree possible devoid of serious interruptions, pain, and danger to the patient. The construction of the instrument is already familiar to many. It has stood the test of practical operation in many cases during three years, at the clinic of Dr. Beach, at the Massachusetts General Hospital, and in my own out-patient and private practice.

The dilator consists of a split guiding staff (Fig. 2) which is best first introduced after being screwed to a flexible capillary bougie guide. Over this guide the dilating staffs (Fig. 1) are passed. These are grooved anteriorly to their centre for passage over the guide, after the invention of Bigelow, but contain a central fin or plate, which is so placed that it slides between the two blades of the guide (Fig. 3). Therefore if the guide is first introduced the dilator must pass within the stricture. This is what, as before stated, insures the entrance of the dilating staff within the stricture and makes the operation of the instrument mechanically certain. When using the dilator in working on strictures of larger calibre, a bulb of 16 F. calibre is furnished, which may be screwed to the end of the guiding staff for its readier introduction past small folds and pockets, in which the small point

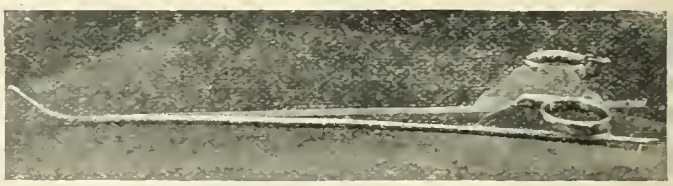

Fig. 2.—Central Fin or Plate.

used in the primary operation is so readily engaged and obstructed.

The handle of the guide is so arranged that with the forefinger passed through the ring farthest from the operator, and the ring placed against the base of the thumb, the hand with its ulnar side resting against the pubes, holds the instrument firmly in position and precludes all possible accident of perforation or other injury to the bladder, such as may occur with an instrument not thus fixed in position (Fig. 4).

The instrument is made with a simple, metallic holding frame (Fig. 1), gauged by the French scale, and suited to boiling or steam sterilization. Codman & Shurtleff, Boston, makers.

In relation to internal urethrotomy with any of the ingenious modern urethrotomes, I would simply say that

Fig. 4.—Showing Use of Guide.

this operation has the one apparent advantage of a more rapid result, but is, after all, nothing but one method of making a rapid dilatation of the stricture, by assuring that the cut or rupture of the callus takes place in one direc-

tion, as indicated in Fig. 5, a modified plate after Dittel.

Now, this is just what should not occur, as the divisions of the callous tissue should be as evenly as possible disseminated in the circumference of the mass surrounding the canal. This occurs to a certainty through the process of intermittent stretching, as those fibres which are carried beyond their point of resistance must yield and break away. Now this yielding does not, as one might casually think, take place in the shape of any rough tear when properly done, but in fine lines, which look like a scarification beneath the mucous membrane, the latter often failing to be broken in any way, even in cases where a full and rapid divulsion has been done.

Internal urethrotomy would be useless unless immediately followed by the passage of as full-sized sounds as the individual case would admit, as the part would close and heal together, just as a cut meatus, when left undisturbed, closes together and unites by first intention in a short time.

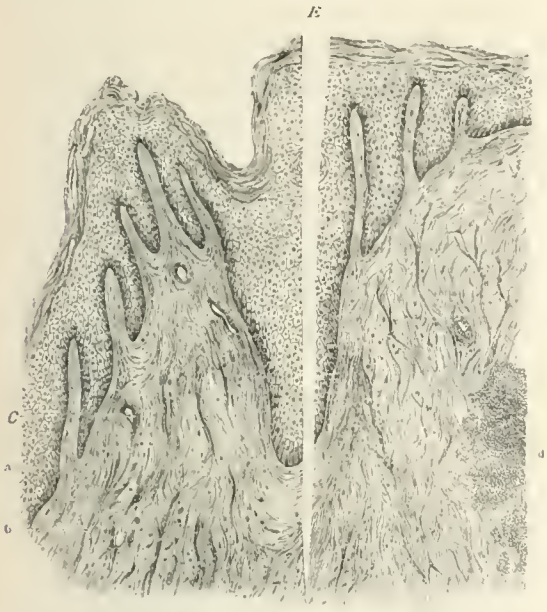

FIG. 5.—Cross Section through a Urethral Stricture. Hartnack Oc. 3, Obj. 4 Modified after Dittel. a, Epithelial layer; b, new growth of connective tissue; c, blood-vessel; d, cell infiltration; E, representation of urethrotome incision such as would be later spread open by passage of sounds.

My colleague, Dr. F. S. Watson, who has been ever ready with fair and helpful criticisms of my work, suggests that, according to Sir Henry Thompson's experience, his own, and that of others, slight interference with these tight strictures often gives rise to more serious disturbances than the most radical measures, and that this fact might offer a serious objection to the method of rapid intermittent dilatation. This, I agree, would be a valid reason against the operation, were we not able to explain it away. The fact is, we do not interfere slightly, but to a considerable degree, so that, whatever amount of congestion and swelling may result from the stretching, we always proceed far enough to leave our patient with a urethra of sufficiently improved calibre to allow him to evacuate his bladder with comparative freedom—this, as before stated, being generally accomplished at the first sitting by a dilatation of from 16 to 18 or 20 F., according to the amount of resistance and normal calibre of the individual case.

In conclusion, if the foregoing has established anything, it is that the full and immediate divulsion of urethral stricture is no longer a necessary or warrantable operation.

The Maryland Medical Journal comes out with the beginning of a new volume, the thirty first, in a new dress, presenting a much better appearance than before. The contents of the journal are as good as ever, and that is saying a great deal. We congratulate our esteemed contemporary and wish it a long and successful life.

Clinical Department.

SUPRAPUBIC CYSTOTOMY FOR VESICAL HEMORRHAGE.[1]

By WILLIAM S. CHEESMAN, A.M., M.D.,

AUBURN, N. Y.

My patient was a strong, well-nourished man, aged twenty four, who for some three years had been subject to attacks of hæmaturia. These were often severe, but had always, after a week or so, ceased spontaneously. They occurred usually in the winter, and were accompanied by pain in the back, which was felt most when the bladder became blocked with clots, urination being thus rendered difficult. In the interval between attacks he felt perfectly well, and worked at a mechanical trade. The family are strong Scotch people, and their history throws no light on his case.

I was called to see him first on February 13, 1893. He was unable to urinate, and the bladder was distended. The catheter afforded partial relief, by giving exit to some bloody urine and small clots. After catheterization bleeding was freer than before, and the catheter had to be employed several times in the succeeding twenty four hours. Vesical tenesmus compelled the patient to spend much of his time straining in the endeavor to expel clots. I then had him transferred to the Auburn City Hospital for better observation.

On February 14th he was etherized, and I examined the bladder with a Thompson's searcher. Nothing was found, and the bleeding was made more severe. Indeed, it soon became alarming. In a single night he would fill an ordinary vessel with urine and blood. As the amount of urine was never excessive either before or after, it is fair to conclude that fully half of the above amount must have been blood. Large fresh clots formed in the urinal, and smaller black clots passed from the bladder. The patient had no pain except when the urine could not pass, and the catheter was of little use, as it quickly plugged.

Accordingly, an exploratory suprapubic cystotomy was proposed and accepted. He had been assured by one of the many physicians whom he had consulted that a vesical tumor was the cause of his trouble, and this seemed also to me the most probable explanation of the case.

On February 20th he was etherized, and the exploratory operation done under strict asepsis. A pear shaped rubber bag was introduced into the rectum, and distended with 8 oz. of Thiersch's solution. The bladder was injected with 6 oz. of the same. The bladder was thus thrown up against the anterior abdominal wall, so as to be clearly visible through it. I did not employ the Trendelenburg posture, though in another case of similarly grave hemorrhage I would certainly do so.

The usual longitudinal incision was made down to the bladder, close above the pubes. The peritoneum was not seen during the operation. On incising the bladder, a large quantity of blood and clots and water gushed out. The hemorrhage which had been taking place could now be correctly estimated. Bright fresh blood welled up from the cavity, and defied attempts by sponges and hot water to stanch it. Nothing could be seen because of the blood which filled the bladder as fast as it was washed or sponged out. The finger, swept around the interior, detected no tumor, stone, or morbid condition of any sort. I therefore tamponed the cavity with plain gauze, and made pressure. This checked the flow, and on removing the gauze slowly under good illumination by a head-mirror, I could see that the blood escaped from a large varicose vein near the apex of the trigone. Here was a deeply red, congested area, with the dilated vein in its centre, on whose surface an ulcerated opening existed, through which blood was still flowing briskly. A good

[1] Read before the Onondaga Medical Society, March 6, 1894.

exposure and rapid sponging, followed by pressure on this spot by a gauze plug in a long sponge-holder, and the bleeding was under control. After waiting to assure myself of this, I applied Monsell's solution freely over the surface of the varix, and bleeding definitively ceased. I considered the advisability of also searing the surface with the cautery, but as the varix extended directly up to the internal urethral opening, I feared, perhaps needlessly, that I might burn more than the diseased area and cause a stricture, and therefore refrained. The wound was closed up to the glass tubing used for siphon drainage.

The patient was, as will be imagined, taken from the table in a condition of severe anæmia; but, as there was no recurrence of hemorrhage, the blood losses were rapidly made good. For many days I feared return of bleeding, but none came. The urine drained clear, and the bladder was washed daily with Thiersch's fluid. The sole unpleasant feature following the operation has been a urinary fistula, which persisted for many months, closing for a fortnight only to break open again, and which has been definitely healed for some two months only. The patient is now well and able to work.

Three things seem worthy of emphasis in connection with this case:

First, the rarity of varices of the male bladder as a cause of hæmaturia. In pregnant women the bladder, like the vagina, vulva, and lower extremities, is liable to varicosities, which have been known here, as elsewhere, to rupture. But in men this condition, while recognized as a possible cause of hemorrhage, is uncommon. It is mentioned in but few text-books of surgery, and in current literature reports of cases are hard to find.

In the second place, I have been impressed by the commanding advantage given by the suprapubic opening. Ten years ago, Sir Henry Thompson and Mr. Reginald Harrison were arguing for the perineal incision in explorations of the bladder, and the protests of Professor Guyon, of Paris, in favor of the suprapubic, gained little hearing in English-speaking countries. The consensus of surgical opinion now favors the *sectio alta*, and justly. In such cases as the one which I have had the honor to report to you, the perineal opening could have given no information whatever, and must have been supplemented by the suprapubic, or the patient would have succumbed to loss of blood. It was absolutely needful to see the bleeding point, for touch told nothing. But with the bladder open and illuminated for visual inspection, one is master of the situation, and curettement, removal of morbid growths, cauterization, the tamponade, can be carried out with exactitude.

In the third place, experience in this and some other less fortunate cases of cystorrhagia, has impressed me with the importance of operating promptly when the bleeding is free enough to be dangerous, and when it is clear that it comes from the bladder. I can give hearty endorsement to Poncet's recommendation[1] that "Epicystotomy," as he terms it, should be done in every case of grave vesical hemorrhage, for purposes of exploration and treatment.

A CASE OF MONSTROSITY.[2]

By THERESA BANNAN, M.D.,

SYRACUSE, N. Y.

Mrs. R——, aged twenty one, primipara, came under observation April, 1892. She was short but well proportioned, and gave a history of perfect health, both preceding and during pregnancy. About the middle of pregnancy, she received a shock on hearing of the death by violence of a cousin. Examination of patient found normal condition, except for a slight presystolic cardiac murmur. Family history showed the mother an invalid since birth of patient, who was her only child.

Labor began at 3 P.M. On examination at 10 P.M., found uterus very large and evenly distended, filling the whole abdominal space to ensiform cartilage. The irregularities of the fœtus were but faintly suggested, nor could the head be outlined. Two small, comparatively hard masses were found, one in the right iliac fossa, the other near the fundus. Faint, hollow sound, resembling the fœtal heart, was heard only in extreme right lumbar region.

On internal examination the os was found dilated to the size of a dollar, membranes bulging and constantly tense. No presenting part could be reached, but the sensation of an exaggerated ballottement was given. As the presentation could not be determined, the complete dilatation of the os was awaited. Then the membranes were ruptured and about two gallons of fluid gushed forth, producing slight shock to patient. Examination then showed fœtus engaging as in face presentation, chin to the rear. Neither the chin nor forehead could be outlined by the finger, and the position was constantly varying. Progress was rapid, and twenty minutes after rupture of membranes the fœtus was expelled. Pulsations of cord continued for a few minutes, and soon the placenta was expelled.

Fœtus was anencephalous. Development of bone extended to the level of an inch above the base of nose. Vertex entirely absent, but cavity of skull was filled with a reddish, jelly like mass, clinging to its base. Face red and swollen, eyes bulging, giving a specimen of what is called the frog-face variety. The under surface of the chin was on a plane with anterior surface of cervical vertebræ, and the abdomen protruded in the form of a cone, with the apex at the umbilicus, where the defective muscular development left an opening two inches in diameter and covered only by a thin membrane, continuous with the umbilical sheath. The head was held in forced extension in contact with the back of the child. Lifting it, the spinal cord and nerves, as far as the eighth dorsal, were exposed, all bone development having been arrested in posterior spinal arches. The sacral curve was prominent and included some of the lumbar vertebræ. All the joints were rigid. The monster was about fifteen inches long and weighed two and one-half pounds.

This case is presented not for its rarity, but to excite a more general interest in teratology.

In the average physician the birth of a monster now and then produces little interest. But at present the intense interest in embryology and comparative anatomy demands a response from the general practitioner who, in spite of the tendency to specialization, still performs the duties of obstetrician. The wonderful phenomena of generation reach the climax when a new being is ushered into this world of ours, but awe quickly gives way to horror when we find, as the result of gestation, instead of a "human form divine," that which the Romans called monster.

The mind, accustomed to the repetition of normal procreation, has, in all ages, been disturbed by deviation. The race to whom "sound mind in sound body" was the beginning and end of philosophy, looked upon deformed infants as ill omened, and soon rid themselves of the unwelcome beings. The warlike Romans considered them as warnings of disaster. Troublous times were accompanied by reports of monstrous births, both human and brute, and the discovery of abnormalities in the entrails of sacrificial animals. The wisdom of Egypt included such superstition, and the folk-lore of every country repeats it to-day in the belief in the influence of spirits or the crossing of species. The "great Pan" and the Satyrs were half men, half goats, while the Minotaur and Cyclops, the "monstrum horrendum, informe, ingens." of Virgil, portray popular belief.

Down the centuries extends this influence, until the spirits shall he exorcised by the calm majesty of science.

In the early part of the eighteenth century teratology approached the classical through the efforts of Geoffroy St. Hilaire. Monsters by excess and deficiency, by fusion

[1] Mercredi Médical, 1892, No. 48.

[2] Read before the Onondaga County Medical Society, December 19 1893.

and parasitism, are some of the classifications found. Every conceivable form may occur, every organ of the body has, at some time, been wanting, and curious misplacements of the internal organs have been found.

With the advance of experimental embryology, a classification from cause may be made. At present our knowledge is hypothetical. In the vegetable kingdom monstrosities are produced by the destruction of parts of buds by birds or stings of insects. Experiments on the lower animals show that, by mechanical separation of the cells, resulting from the first cleavage of the fecundated ovum, twins will be produced, normal in structure, but one half the normal size; that monstrosities occurring naturally may be reproduced by mechanical interference with the cleavage, or by the destruction or wounding of some of the cells, the resulting malformations being in proportion to the extent of destruction. Again, monstrosities occur from the entrance of more than one spermatozoon into an ovum whose power of resistance has been weakened by interference. Moreover, naturalists declare the whole embryonic period of the lower forms of animal life scarcely differ at all, and claim that by going still farther back in the history of development, a period is reached in which no appreciable difference can be discovered between the embryos of the various departments of the animal kingdom. Hence the significance of embryological experiments. For although the various cells must possess the power of differentiation to produce their peculiar kind, the mechanism is probably identical. Consequently, in the human embryo we would expect malformations from interference with any stage of development; the earlier the interference the greater the deformity.

Primarily, a normal embryo depends upon a perfect ovum and spermatozoon. Subjects of syphilis, chronic alcoholism, and other constitutional affections, transmit these tendencies through a single cell.

After the passage of the fecundated ovum into the uterus, any cause which would produce its partial separation from the mucous membrane, and thus interfere with its nutrition, may produce malformation. Among these causes may be included inflammation, attempted abortion, and any form of intense emotion. Maternal impression has always been held by the laity as a frequent cause of monstrosity, but scientists are apt to reject popular theory. Yet, if the functions of the uterus may be suspended by fear or home sickness, or other minor impressions, it would not seem strange if a profound psychic impression of the mother disturbed the ovum resting upon the membrane of the uterus. It seems proper to remain at least receptive while investigations of occult forces are active.

A frequent concomitant of monstrosities, as in the present case, is hydramnion. Whether one produces the other, or whether both are dependent on some other condition, is not yet determined.

Though medical science may never be able to prevent monstrosities, and diagnostic acumen fail to relieve a woman from the paradoxical condition of a fruitless pregnancy, still medical pride will wish to make a pathological equation when the sum of prophylaxis and diagnosis equals zero.

593 Warren Street.

TREATMENT OF PNEUMONIA.

By RAWLINS CADWALLADER, A.M., M.D.,

FALL RIVER MILLS, CAL.

I notice in the Medical Record of February 3d that Dr. E. E. Reichard, of Poughkeepsie, has opened the time-honored discussion as to the treatment of pneumonia again.

His plea for the use of ammonium carbonate is a good one, but I hardly think we can throw aside digitalis yet, or use aconite. No two cases require the same treatment in this malady, and good nursing here tells as in no other disease. To give a heart depressant after the first stage is fatal, and the rapidity of the change is wonderful. Four hours frequently show consolidation of the lung and the beginning of the second stage. The use of aconite is therefore limited, under the most favorable circumstances, to one or two doses. Through the second stage all we can do is to support the heart and stimulate the patient to a crisis. Here ammonia comes in, not so much for its action on the exudation, for it is doubtful whether it can in any way alter an organized exudation or not; but it is a heart stimulant.

Digitalis is our most powerful heart tonic, and we cannot afford to lose its benefit. True, it raises arterial tension and contracts the capillaries, which is to be avoided, but this can be obviated by combining it with nitroglycerine, itself a heart stimulant. In the stage of liquefaction and disorganization of the exudate the ammonia compounds undoubtedly do service and aid its expulsion.

For the first stage, counter-irritation and bleeding; for the second, digitalis and nitro-glycerine; for the third, ammonia and alcohol.

For the sake of suffering humanity don't weaken the patient's already overworked heart. Rather than prescribe heart depressants, let him alone and give him a chance for his life.

SOME NOTES ON AURAL DEVELOPMENT IN A CASE OF CONGENITAL DEAFNESS.

By WALTER B. PEET, M.D.,

HAMMONTON-IN THE-PINES, N. J.

For some time past the theory has been gaining ground in this country, Germany, France, and England, that latent hearing may be developed by massage of the ear by means of sound vibrations. A number of specialists and some schools for the deaf have given the subject considerable attention.

In November last a boy, very bright, eight years of age, congenitally deaf, and born of deaf parents, came to me for instruction. His family said that an attempt to develop hearing would be useless, as he had been examined by a number of specialists and found to be totally deaf. As the case was interesting in that the boy was a congenital deaf-mute, whose parents were also deaf, and because of his brightness, I tried to develop hearing: I began on his arrival to use with him for a short time each day an American conical conversation tube. For somewhat over a month the exercise of each day consisted of loud sounds of different pitch—shouts, whistles, chords on the piano, etc., produced near the mouthpiece of the tube; after which the words: "the key, the hat, the box, the mat, the jug, the saw, the adze, the cup, the vase, the door, the quill, the knife," were plainly spoken through the tube, the pupil facing me, reading my lips, and repeating the words. (The above twelve words contain all of the letters of the alphabet. It is hardly necessary to say that they do not include all of the sounds.)

The first sign of encouragement came when the boy complained that the loud shouts were beginning to be disagreeable. I then spoke the words "cat" and "dog" several times loudly and plainly, through the tube. He read them from my lips and repeated them, after which he turned his back, and repeated either word whenever I uttered it at the mouthpiece of the tube. After drilling on the words "cat" and "dog" for a few days a third word was added, and he has at this time become able to differentiate between and repeat eight words when spoken through the tube. The sound and meaning of a new word is taught every few days, and he is taught to articulate it. (With a person who has never heard, it is necessary not only to develop the hearing apparatus so that the brain is conscious of sound, but the brain must be educated to recognize the difference between sounds, and this must be done very slowly and gradually, as in the case of the infant.)

The shouts, etc., described above, are gradually decreased as the boy's hearing improves. He now puts

the mouthpiece of his tube in the piano, over the strings, and enjoys the music when a person plays.

EAR COTTON—SALMON COLORED.

By GEORGE E. ABBOTT, M.D.,
NEW YORK.

THERE are few appearances more unpleasant than the ordinary white (?) cotton stuffed into the ears of patients; and the more refined the patient, the greater the seminausea one experiences, and the greater the embarrassment of the patient.

For the sake of æsthetics in this matter, Messrs. Dennison & Co., of this city, have prepared for me some salmon colored absorbent cotton, which is so nearly the color of the auricle that it is difficult to perceive it in the ear. The patient leaves one's office neat and comfortable, knowing that she is not attracting repulsive pity from the public.

I know this "practical suggestion" will be criticised by some, with the remark that many of the best aural surgeons do not allow any cotton in the ear, that it interferes with both ventilation and drainage. It must have been such an one's patient who complained to me a few days since that "Dr. So and So syringed my ear with warm water and then sent me right out into the cold wind. I suffered dreadfully all the way home and all night."

Patients know from experience what lends comfort to their nerves, and we know from scientific experience that whatever comforts nerve-filaments is good and sound practice, theorists to the contrary.

A small amount of absorbent cotton lends comfort to the ear and brain in cold, windy, dusty weather, and if frequently renewed, it will increase the drainage by its capillary attraction. It will control the odor and avoid the necessity of ventilation.

We do not ventilate our surgical wounds; but by every means possible avoid the access of the microbian air. Why not do the same for middle-ear diseases, and dress them surgically often enough to provide for ventilation. I believe surgeons, patients, and the public will welcome the use of salmon colored cotton as an ear-dressing.

125 WEST EIGHTY-SECOND STREET.

TROPHIC DISTURBANCE OF THE FINGERS.

DR. W. DAVIDSON BIDWELL, of Leavenworth, Kan., writes: A girl, of Swedish descent, about twenty years of age, ruddy cheeked and healthy looking, presented herself at our office during the winter, complaining of stiffness and pain in her left hand. All the fingers were stiff, slightly enlarged, and so hard as to resemble sclerodermia, especially toward the tips. The thumb was considerably swollen, and the skin thickened and very tense. Lancinating pains shooting toward the wrist had been quite severe, more particularly in the thumb; and she had found that, by whittling the skin off over the tips of the thumb and fingers, the pain was much relieved. Ten years previously she had had a felon on this thumb, and the hand had been more or less affected since.

After poulticing the thumb several days, a free incision was made in it and a small accumulation of cheesy material removed. Poulticing was resumed, and the fingers became somewhat more flexible and less numb; but when she made her next visit, coming in several miles from the country town where she resided, dead bone could be felt with the probe, and I removed the last phalanx of the thumb. April 5th she appeared again. The wound had healed nicely, leaving a serviceable stump, and all hardness and stiffness had disappeared from the fingers, which are now as sensitive and serviceable as those of the other hand. Since the removal of the partially necrosed phalanx her hand has come back to its normal condition; whereas, previous to treatment, she was, to use her own words, "in the habit of whittling off her fingers daily as one would a stick of wood."

Progress of Medical Science.

The Nervous Complications of Measles.—At a recent meeting of the Royal Medical and Chirurgical Society, London, Dr. Dawson Williams drew attention to certain complications of measles and other infectious diseases which are apt to be extremely puzzling, and the nature of which has been but little understood; he took as his text a case in which, on the fourth day of an ordinary attack of measles, convulsions occurred followed by "unconsciousness," lasting ten days and leaving a condition of general paresis and loss of speech, with tremor and inco-ordination. A gradual improvement ultimately took place, but the patient was left in a state of intellectual backwardness, and presenting many of the symptoms of disseminated sclerosis, with a spastic condition of the lower limbs—a "false disseminated sclerosis due to measles." By reference to cases recorded by various observers in connection with other infectious diseases, it was shown that, possibly from the virulence of the poison during the onset of the malady, widespread lesions of the nervous system, principally originating in its vascular supply, were apt to occur, not only causing serious symptoms at the time, but doing permanent injury to innervation. The onset of coma and convulsions during the course of a febrile infectious disease should not then be looked upon as generally indicating any accurately localized mischief, such as hemorrhage; nor should consecutive tremors and pareses, discovered after cessation of more serious symptoms, be looked on as descending degenerations likely to end in atrophy and contracture; but the cerebral symptoms should be regarded as pointing to only a part, although the most demonstrative part, of a widespread implication of many areas in the nervous system, and it should be remembered that, the injury once done, a gradual recovery, the limits of which it is at present impossible to define, may slowly take place, separating these cases in a marked manner from those of true muscular atrophy, or true disseminated sclerosis, the progress of which is usually in the opposite direction—a distinction worth remembering.

Auto-Suggestion in Nervous Dyspepsia.—Before the *Association médico-pharmaceutique* of Berne, Dubois recently called attention to the mental attitude of certain nervous dyspeptics concerning diet and treatment. Persons with organic gastric troubles are generally very submissive. They seldom rebel, except when some dietetic preparation is peculiarly distasteful, or when limitation in regard to favorite dishes, alcoholic beverages, tobacco, etc., seems too rigorous. They are perfectly aware of the beneficial results of strict rules, yet are wanting in the courage to persist with a special diet for any great length of time. Patients with nervous disturbances of digestion appreciate highly anything referring to food. Their own ideas are formed concerning the digestibility of this or that, and their perseverance in some self-chosen diet and treatment is worthy of a better cause. Milk cannot be tolerated; one drop in tea induces intense suffering. Bread is insupportable, except in the form of toast or biscuit. Butter is often said to cause oppression, and fruit and vegetables may not be tasted for years. They do not improve, they emaciate, sleep and digestion are defective. Yet in spite of this failure to mend, their morbid perseverance continues. It is really a psychic phenomenon. In it exists the characteristic auto-suggestibility of hysteria and allied neuro-psychoses. Unless the method of treatment imposed by the physician meets with rapid success, these nervous dyspeptics lose patience and will have none of it, though restrictions in diet originating with themselves are rigidly adhered to for years. The patient grows nervous because she gets weaker; and the nervous disturbance increases the physical weakness. The vicious circle is thus maintained for months and even years.

To overcome the difficulty by speedy improvement at

first, and later by getting a good grip on the patient, constitutes the surest method of being truly helpful. Remedies to improve nervous tone, the use of water and exercise, judicious rest, and novelty in the way of amusements, are excellent aids. Subgallate of bismuth, five grains three times a day, as recommended by Flint, promptly relieves the dyspeptic symptoms. It may be given before or after meals. In some cases it seems to act more favorably when taken before meals, and in others when it is given after meals. Water, in the form of the cold effusion, is one of the best tonics. When there is no shower, the bather can use a small pitcher, holding the spout over the back of the neck, and by bending a little forward, allow the water to fall over the spine and other parts of the body. A convenient way is to fill a pail with cold water before stepping into the tub, and dipping it out with the pitcher. The patient may stand in several inches of hot water, and thus keep the lower extremities warm. For the insomnia, want of appetite, shallow breathing, and general nervousness of functional dyspepsia, there is no single remedy so good as water.

Urethro-vaginal Abscesses.—In a study of the tumors of the urethro vaginal septum Dr. T. S. Cullum, of the Johns Hopkins Hospital, describes the usual symptoms as beginning with painful micturition, which increases for a few days or months, when the severe pain begins to be followed by a sudden discharge of ammoniacal urine or pus, which gives immediate relief. A swelling is now noticed in the vaginal vault, from one to two centimetres behind the external orifice of the urethra. The tumor is fluctuant and tender, varying in size from a marble to a hen's egg. On pressure the size is diminished, and ammoniacal urine or pus is discharged from the urethra. By introducing a catheter along the anterior wall of the urethra it will enter the bladder with difficulty, and clean urine will usually escape. The sac cavity may be entered by introducing the catheter along the urethral floor, with the point directed downward. The patients give no history of chills, and are usually in good health. The change from a sitting to a standing posture will often cause the contents of the sac to escape, but the patient notices only the moistening of the clothing. Coition may be painful, and may also cause a discharge of the sac fluid, which may escape into the bladder. The genitals and thighs may be excoriated when the discharge is irritating. Calculi may be found in the sac. Among the possible causes may be congenital cysts, or those occurring in the new-born. A weak point in the urethral wall may permit the formation of a true urethral diverticulum. There may be an accumulation of secretions in a urethral gland. A lacuna of Morgagni may be dilated, probably by inflammation, closure of its orifice, and subsequent distention with secretion. Skene's tubules may be dilated, and possibly occluded. A dilatation may be formed in the urethra by an arrested calculus. An abrasion of the mucous membrane may give the urine access to a small pocket to decompose and set up an inflammatory process. A suppurating cyst located in the urethro-vaginal septum may burst into the urethra. Cysts of Gartner's duct are usually about the size of a pea, and do not communicate with the urethra, so that it is generally not difficult to differentiate between them and these sac-like dilatations in the urethral floor. The patients were successfully treated by carefully excising the sac, and closing the opening with silk sutures.

Arterio-sclerosis after Syphilis.—According to the Berlin correspondent of the *Medical Press*, Dr. Fraenkel gave an address recently on this subject. He said the question of the origin of aneurisms, so far as syphilis was concerned, had been very variously answered. Walsh was of opinion that syphilis was the foundation of aneurism in 60 per cent. of the cases, other writers went further and put the percentage at 80. The speaker had carefully observed clinically nine cases of aneurism during the past four years, and had the opportunity of an examination post mortem in every case. Five were women and thirteen men; four were over sixty years of age; ten were under fifty, six below forty. The remark had been already made that in proportion to the ordinary arterio sclerosis of old age aneurism was met with at a relatively early age, principally from the middle of the twenties to the end of the forties. This circumstance made it possible that some special condition must be in action. Among the speaker's 19 cases syphilis was certainly present in 10, in six of the patients under fifty, and four of those under forty. The proportion of syphilitic cases in his series was, therefore, about fifty per cent. As to the mode of origin of true aneurism different theories were propounded, especially two which had been called the mechanical theory and the inflammation theory. The mode of origin was of importance when we had to decide whether an anomaly of constitution was to come into consideration or not. Anatomically the mode of origin was very difficult to determine, as we could not determine whether the arterial changes were syphilitic or not. The preparation shown was of special interest, inasmuch as it was not a true aneurism, but an advanced and very extensive arterio-sclerosis in a comparatively young person, in whom undoubted anatomical changes of cardiac syphilis were present. A woman, aged thirty seven, was admitted under the speaker's care last year with symptoms of valvular insufficiency. The patient frequently complained of headache, pains, and attacks of faintness. She was discharged improved. The diagnosis was aortic valvular insufficiency, resulting from an antecedent reticular rheumatism. The husband of the patient was syphilitic. The patient had suffered from swellings of the head that had burst, and the cicatrices were still visible. At the commencement of the present year the patient returned with symptoms of cardiac trouble which differed from that present before in being characterized by violent attacks of angina pectoris. The patient did not come out of one of the attacks. The anterior and left coronary artery were quite permeable and unchanged, the right was totally obliterated at its point of entrance into the aorta by an extensive arterio-sclerosis. That these changes were of a syphilitic nature was shown by the presence of a large cardiac gumma.

What Physiology Owes to Medicine.—Medical men are justly proud of the fact that the most thoroughly investigated divisions of biology are those which relate to human physiology. As human life and health are the most valuable possessions, they have been carefully studied for ages, and are to-day receiving the greater part of all biological research. Dr. Frederic S. Lee, in the *American Naturalist*, declares that to the medical fraternity, more than to any other one class, does the science of physiology owe its great progress in the past. It has, however, widely overstepped its early medical boundaries, largely through the efforts of its medical promoters, who realize the necessity of studying other living beings for the light thus thrown on human physiology. It has become a biological science, having developed beyond its medical and anthropological fields. Human physiology, like human anatomy, will necessarily always form one of the foundation-stones of a medical training, and perhaps the most important one. Animal physiology presupposes anatomy, and each science has its own field and its own methods. Human physiology, however, is but one branch of a science as broad as the domains of protoplasm. The human body is a machine, but it is a machine that has had a history. To learn to know the mechanical, chemical, and physical laws of this most complex of vital mechanisms is an achievement. But to know the action of the mechanism without its history is not merely short-sighted, it is impossible. For this reason a school of general and comparative physiologists is arising. Besides great advances on well-proved lines, physiology is fast developing along broader biological paths. In the interests of humanity the tendency of biological thought is to centre upon the healthy workings of the human body, and this tendency is much encouraged by both the physician and the surgeon.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street

New York, June 23, 1894.

THE TRIUMPHS OF MODERN SURGERY.

THERE appear occasionally criticisms of modern surgery, in which efforts are made to show that the human body is attacked too frequently and too eagerly by the surgeon of to-day. Instances do undoubtedly occur in which judgment is obscured by excessive zeal; but, taken as a whole, the results of modern surgery in the saving of life are little less than marvellous when compared with the work of older days. A writer in *The British Medical Journal* has brought together some interesting and timely statistics bearing on this point.

"Some of the best work," he truly says, "is of such recent growth that we have no past record with which to contrast it; we cannot contrast our pictures with blank canvas. If we take, for example, renal surgery, and look back only fifty years, we find Lawrence saying, 'The kidney, gentlemen, is fortunately beyond the reach of the surgeon.' If we take the surgery of the vermiform appendix, we find nothing, less than fifty years ago—nothing but deaths. So, too, with the radical cure of hernia, and with the surgery of the brain. Barker's 50 consecutive cases of the former without a death, Macewen's success in 16 out of 17 cases of cerebral abscess, and in 16 out of 20 cases of thrombosis of the lateral sinus, 'we look a few years back, and we seem to be in another century.'"

If one takes operations of which comparative statistics are obtainable the results are just as striking. Thus Dent's statistics of St. George's Hospital for amputation show that between the ages of thirty and forty the mortality during 1872–1874 was 40 per cent.; during 1874–1888 it was 14.2 per cent. From 1874 to 1879 the percentage of mortality after amputation, at all ages, was 26.3; from 1880 to 1888 it fell to 18.8; and of these latter years he says: "If we exclude the cases of death already tabulated as not really due to amputation, we are left with 21 deaths in 341 cases, or a mortality of about 6 per cent." During 1852–1874 there were 500 cases of amputation, and 75 of these died of pyæmia; during 1874–1888 there were 400, and 8 of these died of pyæmia. Mr. Page's statistics of the Newcastle-on-Tyne Infirmary show, during 1879–1888, 484 cases of amputation, with a general mortality of only 7.6 per cent.

The mortality from all amputations in the Crimean War was 63.5 per cent.; in the American Civil War, 48.7 per cent.; in the University College Hospital in 1875, it was 16 1 per cent. This percentage has steadily fallen until, in 1890, it was only 6.9 per cent., while the mortality from major amputations was only 9 per cent. Furthermore, the relative number of amputations compared with all other operations has steadily fallen from 14.8 to 2.5 per cent. The mortality from ovariotomy has fallen from over 50 to less than 10 per cent. The same story might be told as to compound fractures, excision of joints, laparotomy, and extirpation of the uterus.

THE SHORT STORY AND NERVOUS DISEASE.

EXCEPT supreme grief, perhaps nothing in the world so effectually takes the sweetness out of life as the constant daily association with mental and nervous disease. The endless argument, the deadly introspection, together with the exaggerated selfishness common to nervous troubles, strains human endurance to the utmost degree. Any hint that can render the tax less severe constitutes more than an ordinary boon.

One way to change the current of unpleasant thought is to present in bright and attractive form the original and engaging thoughts of others, and thus substitute some other emotion. This is best done by the short story, in which American writers excel. It chains the attention without straining it. The short story can be finished at one sitting, and the subject upon which the mind is fixed remains vivid in its entirety. This strengthens the weakened will and increases the power of strict attention. A discussion of plot and character may follow, and thought is kept in the new channel a little longer, though with a slackened grip that avoids fatigue. Interest is aroused, and the habit of looking outward is begun and each day strengthened. What though a relapse into argument, introspection, depression, and colossal selfishness is sure to follow? Even a brief banishment of these joy-killers is the beginning of improvement.

After a time the patient may be called upon to read aloud, instead of being always read to. This rouses other forces beyond mere interest and fixed attention. Reading aloud expands the lungs and calls many muscles into use. The utmost tact is necessary to create a desire in the mind of a nervous invalid to read aloud or to perform any act that has in it an element of self sacrifice. Such a person may impulsively deluge with favors the favorite of the moment. But it is most difficult to establish a fixed habit of daily doing for others in a small way. Monotonous humdrum goodness is without charm for the nervously weak, and may be slightly beyond their average capacity. A direct appeal to selfishness is about the best way to deal with the situation; bribe the patient to read aloud by the promise of an exchange of favors.

Bret Harte's best work, his best short stories, are simply perfection for this kind of semi medical work. They are distinctly original, and quite outside the beaten track in style and treatment. They are terse to the point of severity, and wholly adequate; everything necessary is told, with great economy of word and phrase. There is no lingering analysis, and the mind is carried at once to the centre of dramatic interest and kept there to the

end. In Mary Wilkins's pictures of New England life there is most shade, and the horizon is narrower. Her short stories are excellent to begin with, and serve a purpose in the way of an entering wedge that few others can attain. Richard Harding Davis has a distinct place in this kind of work, for he writes of the city as it is—the city of the street and of the drawing room—where real men and women live and move and have their being, and rise to the heights of heroism on occasion. Guy de Maupassant at his best is clear of vision and perfect in style. The little volume known in English as "The Odd Number" contains stories that are admirable to break up thoughts that are too persistent. Rudyard Kipling is a master-hand at the short story. But women, as a rule, do not appreciate him. When they do, it is impossible to overestimate the stimulating effect of an "Invention" or a "Plain Tale."

The genius that depicts the true history of imaginary men and women should be recognized as a force for good in the attempted amelioration of nervous states. Mental food must be regulated as well as the material diet and daily habits. Reasonable impressionism, as in the matter here suggested, has been found the best for this particular purpose.

HUMAN OSTRICHES.

The death of a "fakir" who earned his living by swallowing all kinds of non-edible articles occurred recently in the London Hospital At the autopsy the house-surgeon found intestinal perforation and peritonitis due to the presence of a piece of string with corks attached, a piece of leather with a hook at each end, a bullet, tin-foil, and quantities of loose corks.

The *Lancet* takes occasion to cite various cases of extraordinary gourmandizing *a propos* of the London Hospital case.

"There are," it says, "recorded instances of men who have devoured the whole of a sheep or of a sucking-pig raw; and there is one at least of a man, an attendant at the Jardin des Plantes in Paris, who ate the whole of a dead lion. Another Parisian, by name Tarrare, who made a livelihood by swallowing corks, pebbles, apples, and such unconsidered trifles, would occasionally, to satisfy a bestial craving, eat a live cat, and appears finally to have taken to cannibalism. Francis Battalia, who ate half a peck of small stones with his beer every day, served as a soldier in the seventeenth century, and refused other rations. Whatever his particular method of deceit was, he seems to have imposed on the medical profession of the day, and as we are not informed how big the stones were it is possible that they were small enough to cause no inconvenience as foreign bodies, and may have aided in stomachic trituration. The feats of John Cummings, an American sailor, at the beginning of this century, are as wonderful as any, and are generally received as authentic. It appears undoubted that this man swallowed thirty-five clasp knives, and that, although in the end he died in great agony in Guy's Hospital, he lived ten years with a considerable, though uncertain, number of clasp-knives in his stomach."

Glass-eating is one of the favorite forms of abnormal indulgence on the part of travelling fakirs in this country. Clay-eating was at one time an established institution among certain classes of "poor whites" in the South. We believe that under better conditions of existence the custom has been largely abandoned. The clay was supposed to have some nutritious properties, but in fact its effect at first was to lessen the normal pangs of hunger. Later, the clay-eater acquired a degree of fondness for this form of diet.

The fatalities from swallowing inorganic objects for the purposes of a show have become now so numerous that boards of health or the anti-suicide law might properly be invoked to prevent such dangerous and idiotic exhibitions.

ANOTHER MALPRACTICE SUIT COMES TO NAUGHT.

One of the many dangers to which our profession is exposed is that of a suit for malpractice, brought against the medical attendant by a dissatisfied patient, or one seeking to avoid the payment of a bill which he thinks large. An interesting case of this kind was recently tried before Judge Truax in the Supreme Court of this State.

The suit was brought against Drs. A. H. Goelet and E. V. Delphey, of this city, by a Mrs. Lally, who sought to recover $5,000 damages for alleged malpractice on the part of the defendants in administering chloroform to her husband. The chloroform was given preliminary to an amputation of the finger and, the plaintiff asserted, "against the will of the patient, his wife and children, carelessly and without skill and in such quantity as to cause the death of the patient."

The defendants submitted a full denial of these charges and stated that the chloroform was administered in very moderate quantity, not under positive protest of the patient or his family, and with proper care and skill.

The history of the case, as brought out in Dr. Goelet's testimony and not disputed by the widow, was as follows: The man, Michael Lally, whose family physician Dr. Goelet had been for fourteen years, came to him for treatment of an injury received from a splinter entering the forefinger of the right hand. Gangrene set in and the patient showed symptoms of septic poisoning, so that amputation was found to be necessary. The heart, lungs, and kidneys of the patient were examined and found to be normal. The only protest made by the patient was, "Doctor, you are not going to give me chloroform, are you?" When it was explained to him that chloroform would be used only at the beginning, he said no more. The anæsthetic was administered through an Esmarch inhaler, drop by drop, and less than one fluid drachm in all was used. After taking a few whiffs the patient began to resist and to throw his arms about. The wrist of the side upon which the operation was to be performed was held until the man became quiet. The patient then began to have stertorous breathing, and the chloroform was discontinued for about two minutes until the breathing was normal and signs of returning consciousness became apparent. Ether was then substituted, but the man soon ceased to breathe. His feet were at once elevated, the head and shoulders being suspended over the side of the bed, and artificial respiration was instituted and maintained until it was seen that the man was certainly dead.

A number of the best-known operators in the city tes-

tified that the defendants had followed the best practice of physicians skilled in operating in such cases, and that they (the witnesses) approved of beginning the anæsthetization with chloroform.

An interesting point, and one showing the weakness of the plaintiff's case, was that raised by her counsel, who tried to prevent Drs. Goelet and Delphey from testifying in their own behalf, on the ground that a physician is bound in law to professional secrecy—that is to say, he cannot disclose any information whatever obtained by him in his capacity as a physician. This objection was overruled.

The judge's charge was favorable to the defendants. He pointed out to the jury that there were two facts for them to determine, viz., whether or not the chloroform was administered against the will of the patient, and whether or not it was administered negligently or unskilfully. The fact of the protests of the wife and children against the use of chloroform was aside from the point in law. If, however, the medical attendants had administered chloroform against the will of the patient himself, then they became trespassers and were responsible for the results of their trespass. The evidence showed simply that the man had come to his death in consequence of the administration of an anæsthetic; and unless the members of the jury were convinced that the patient died from chloroform, they could not find against the defendants for the results of a trespass, even if the chloroform had been used against the will of the patient. In regard to the second point, the judge charged that the law requires that physicians and surgeons shall be skilful in their profession and shall exercise reasonable care and diligence proportionate to the importance of the case in hand. But they are not bound to insure success in the operation, for if such were the case few surgeons would be willing to assume the responsibility of operating, no matter how urgently surgical interference might be indicated. They can only be held liable for not exercising due care and skill in the medical and surgical treatment of their patients.

The jury was out only about two hours, and then returned with a verdict for the defendants.

Drs. Goelet and Delphey are to be congratulated upon the result of this suit, yet the hardship is rather that such a suit should have been brought. If a man who for fourteen years has been the trusted family physician is liable to be sued when finally one of the family dies under his care, no medical man is secure. There ought to be some redress for one who has been subjected to the mental distress, expense, and loss of time consequent upon a suit of this nature. Unfortunately he must content himself with the satisfaction of feeling that it might have been worse, and that the sensibilities of the jury might have been so worked upon as to decide the case against him. In the meanwhile, each case in which the physician triumphs goes so far in the line of discouraging other people who think they may evade the payment of their dues or even squeeze a few dollars out of their former medical adviser, by accusing him of incompetence.

Dr. Karl Posner, one of the responsible editors of the *Berliner klinische Wochenschrift*, has been appointed Professor of Internal Medicine in the University of Berlin.

CASTRATION IN HYPERTROPHY OF THE PROSTATE.

Castration for the relief of varied conditions, both in the female and the male subject, has become a popular means of treatment—popular from the handle rather than from the blade side of the scalpel. Men dislike to sacrifice their testes perhaps more than women dread the loss of their ovaries, and in both sexes psychical derangements are not at all unlikely to follow such mutilation, though the importance of this feature has undoubtedly often been exaggerated.

Reasoning from the analogy existing, or supposed to exist, between fibroid growths of the uterus and enlargements of the prostate, it has been thought that since oöphorectomy has been found to lead to a decrease in the size of the tumor in the one case, castration would show equally favorable results in prostatic hypertrophies. Experiments upon animals carried out in Europe, and more recently by Dr. White, of Philadelphia, have demonstrated that the idea is not wholly theoretical, at least so far as the lower animals are concerned. How it will succeed in man remains to be proven; bnt if we can judge from a single instance, just reported to the New York Academy of Medicine by Dr. Smith, of Texas, the method gives some promise of being applicable to certain cases.

A few weeks ago we referred to the suggestion made by Dr. Daniel, that castration be practised as a punishment for crimes committed in obedience to perverted sexual impulse. If this suggestion should meet with ready adoption, a series of valuable observations could be made upon the future of the prostate in those so punished, and especially if some were afflicted with enlargement, as would not be unlikely.

The device recently put into practice here of supplying the place of the extracted gland with a celluloid substitute would assure the consent of such prostatics as might hesitate on æsthetic grounds.

Thus supplied with deceptive evidences of manhood, one could go bluffing through the world without the secret fear, as one patient expressed it who objected to the proposed operation:

> "That the boys on the street would shout,
> 'There he goes with his testes out.'
> Dreading far less that they should call,
> 'See the man with the celluloid ball.'"

It will have to become a pretty firmly established means of relief for prostatic obstruction before castration becomes a fad with patients; though, judging from what has been witnessed in female castration during recent times, it might readily become so with the surgeons.

Gifts to the Medical Department of the Northwestern University.—Mr. William Deering, a Chicago merchant, has made a generous gift to the Northwestern University. Calling at the treasurer's office, he placed on the table a parcel of bonds of the value of $50,000, and said to the treasurer: "Here's something for the medical school." Mr. Deering afterward explained that the object he had in mind was to found a new professorship in the medical department of the university, and to honor his life-long friend, Dr. N. S. Davis, a pioneer physician of the West.

News of the Week.

Mississippi Doctors.—The Medical and Surgical Society of Mississippi was organized at Jackson, May 20th, with one hundred and twenty-five names of prominent physicians enrolled. Dr. J. H. Lucas, of Greenwood, was made temporary president, and Dr. H. H. Hughes secretary. The organization is said to be the outcome of dissensions in the State Medical Association. Governor Lowry welcomed the doctors to the city.

The Iowa Medical Society met at Des Moines. Among the papers read were: "Anæmia of Children," by Dr. Caleb Brown, of Sac City; "Mental Cramp," by Dr. Gresham H. Hill, of Independence; "Castration as a Treatment for Insanity," by Dr. Clifton A. Leech, of Keokuk; "The Duty of the Physician to the Public," by Dr. P. I. Fullerton, of Raymond; "Epilepsy," by Dr. Maxwell; "Errors in Therapeusis," by Dr. G. W. Burr, of Keokuk; "Brain Surgery," by Dr. Fairchild; "Physiology of Education," by Dr. Woods Hutchinson, of Des Moines; "Kidney Tuberculosis," by Dr. C. D. Brookman, of Ottumwa; "The Murphy Button in Rectal Stricture," by Dr. C. E. Ruth, of Keokuk. The following officers were elected: *President*, Dr. A. L. Wright, of Carroll; *Vice-Presidents*, Drs. D. S. Fairchild, of Clinton, and J. G. Maxwell, of Keokuk; *Secretary*, Dr. J. W. Cokenower, of Des Moines; *Assistant Secretary*, Dr. Sampson, of Creston. Creston was selected as the next place of meeting.

The Nebraska Medical Society met at Lincoln. On motion of Dr. W. Ely, of Ainsworth, a resolution was adopted recommending that all that part of the code of ethics referring to consultations and the patenting of instruments be abolished. This resolution was ordered transmitted to the American Medical Association, by whose authority requests were sent to the various State medical societies asking for recommendations and suggestions regarding the code and other questions of importance to the medical profession. The following officers were elected: *President*, Dr. H. B. Lowrey, of Lincoln; *Vice-Presidents*, Dr. J. E. Summers, Jr., of Omaha, and Dr. W. B. Ely, of Ainsworth; *Recording Secretary*, George Wilkinson, of Omaha; *Corresponding Secretary*, Dr. J. E. Lavender, of Omaha; *Treasurer*, Dr. W. M. Knapp, of Lincoln. Grand Island was chosen as next place of meeting.

The Washington State Medical Society elected the following officers: *President*, Dr. Darius Mason, of Spokane; *Vice-President*, Dr. J. M. Sample, of Medical Lake: *Secretary*, Dr. R. L. Thompson; *Treasurer*, Dr. J. B. Eagle, of Seattle; *Censors*—Dr. G. S. Armstrong, *Chairman*; Dr. H. G. Mauzey, Dr. J. M. Semple, Dr. F. H. Cole, and Dr. T. L. Catterson.

A Case of Small-pox in Rutland, Vt.—Last week a traveller from Chicago was taken ill at a hotel in Rutland, Vt., with what proved to be small-pox. The hotel was at once quarantined by the health authorities.

The Medical Society of New Jersey will hold its one hundred and twenty-eighth annual meeting at Lake Hopatcong, June 26 and 27, 1894. An interesting programme has been arranged.

Award of the Boylston Medical Prize.—The Boylston Medical Prize for 1894 has been awarded to Dr. Norman Walker, of Edinburgh, Scotland, for an essay entitled "The Histological Varieties of Cutaneous Cancer."

The New Hampshire Medical Society held its one hundred and third anniversary meeting on June 18 and 19, 1894, at Concord. An interesting programme insured a large and profitable meeting.

The Transactions of the Pan-American Medical Congress.—The "Proceedings of the First Pan-American Medical Congress" were compiled by the secretary-general, Dr. Charles A. L. Reed, and transmitted to the Department of State in November, 1893. By recent joint resolution of the Senate and House of Representatives, the manuscript was transmitted to Congress, and a concurrent resolution has been adopted directing the Public Printer to print the same. The manuscript is now in the office of the Public Printer, and will be put to press at once under the supervision of the Editorial Committee, of which Professor John Guitéras, of Philadelphia, is the chairman.

The Medical Association of Georgia Adheres to the Code.—At the late meeting of the Medical Association of Georgia, Dr. J. McFadden Gaston, of Atlanta, introduced the following resolution, which was unanimously adopted:

"*Whereas*, The American Medical Association, at its last meeting, provided for an expression in regard to the Code of Ethics from the different State Associations, to be laid before the forthcoming meeting at San Francisco, it is hereby

"*Resolved*, That the Medical Association of Georgia reasserts its adoption of, and conformity to, the Code of Ethics of the American Medical Association, as heretofore recognized by that body, and authorizes this record of its adherence to the same."

Treatment of Dysentery.—In the formula for use in the treatment of dysentery, given on page 743, the dose of calomel should have been six centigrammes instead of sixty, as there printed.

The Oregon Board of Medical Examiners has adopted a resolution to the effect that, on and after the first day of July, 1898, it will not grant license to practise medicine on diplomas issued after that date by colleges which do not require that candidates for graduation shall have attended not less than four regular courses or sessions of lectures of at least six months each. The two medical colleges in the State have decided upon a compulsory four years' course of lectures. The "Medical Register" of the State of Oregon now contains seven hundred and forty-six names of licensed medical practitioners.

American Genito-urinary Association.—At the meeting of the American Genito-urinary Association, held at Washington, May 29 to June 1, 1894, the following officers were elected for the ensuing year: *President*, Dr. L. Bolton Bangs, of New York; *Vice President*, Dr. Francis S. Watson, of Boston; *Secretary and Treasurer*, Dr. W. K. Otis, of New York; *Member of Council at Large*, Dr. John A. Fordyce, of New York.

Dr. J. W. Gleitsmann has been appointed laryngologist to the German Hospital, New York.

Dr. Andrew H. Smith, of this city, writes, June 16th: "Will you kindly correct the report in the MEDICAL RECORD, of June 16th, of my paper before the Climatological Association, in the following particulars: 'It was his uniform experience that the motion following an injection [of defibrinated blood] showed no trace of blood' should read 'frequent experience,' etc.; 'man left the hospital apparently well,' should read, 'considering himself well.' In another place I am credited with the statement that the toxæmia in pneumonia resulted from overfeeding. What I really did say was that the existing toxæmia could not be removed by overfeeding."

Montefiore Home for Chronic Invalids.—Drs Leonard S. Raus, Hiram N. Vineberg, and Josephine Walter have recently been appointed attending gynecologists to the institution.

Opium Smokers in New York.—There are about ten thousand opium smokers in New York according to the testimony of one of the witnesses before the Lexow Committee.

Dr. William L. Briggs died on June 14th in Nashville, Tenn., aged sixty-six. He was a member and an ex-President of the American Medical Association. He had been honored by this association on several occasions, being elected a delegate to the International Medical Congress at Rome, Italy. He was President of the American Surgical Association in 1885 and was the author of a number of valuable medical publications.

The State Board of Medical Examiners.—The Regents of the State University have reappointed on the State Board of Medical Examiners, Drs. W. W. Potter, of Buffalo, W. S. Ely, of Rochester, and Maurice J. Lewis, of New York; Dr. Asa S. Couch, of Fredonia, was also reappointed; and Drs. J. Willis Candee, of Syracuse, and John M. Lee, of Rochester, were appointed on the Homœopathic Board. Dr. Lee H. Smith, of Buffalo, was reappointed, and Drs. Orlando Webb Sutton, of Bath, and Melvin H. Nichols, of Worcester, were appointed on the Eclectic Board.

American Medical Association.—The following officers of sections were elected at the meeting in San Francisco: *Surgery and Anatomy:* Joseph Ransohoff, M.D., of Ohio, Chairman; Reginald H. Sayre, M.D., Secretary. *Practice of Medicine:* E. W. Kellogg, M.D., of Milwaukee, Wis., Chairman; W. E. Quine, M.D., of Illinois, Secretary. *Obstetrics and Diseases of Women:* C. N. Martin, M.D., Chairman; F. O. Worder, M.D., Secretary. *Neurology and Medical Jurisprudence:* Daniel R. Brower, M.D., of Illinois, Chairman; William J. Gavigan, M.D., of San Francisco, Cal., Secretary. *Ophthalmology:* Ed. Jackson, M.D., of Philadelphia, Pa., Chairman; H. V. Wurdeman, M.D., of Wisconsin, Secretary. *Laryngology and Otology:* J. F. Fulton, M.D., of St. Paul, Minn., Chairman; T. J. Gallaher, M.D., of Pittsburg, Secretary. *Materia Medica and Pharmacy:* Dr. Welpley, of St. Louis, Mo., Chairman; G. F. Hanson, M.D., of San Francisco, Cal., Secretary. *Physiology and Dietetics:* E. H. Woolsey, M.D., of Oakland, Cal., Chairman; Charles G. Chaddock, M.D., of St. Louis, Mo., Secretary. *Diseases of Children:* E. H. Small, M.D., of Pittsburg, Pa., Chairman; G. W. McNeil, M.D., of Pittsburg, Pa., Secretary. *State Medicine:* L. H. Montgomery, M.D., of Chicago, Ill., Chairman; C. H. Sheppard, M.D., of Brooklyn, N. Y., Secretary. *Dermatology and Syphilography:* A. E. Regensburger, M.D., of San Francisco, Cal., Chairman; D. H. Rand, M.D., of Oregon, Secretary.

The Death of Dr. Middleton Michel, of Charleston, S. C.—The deceased, whose death occurred on Monday, June 4th, was seventy-two years of age, was a graduate of the Medical College of South Carolina, but much of his professional study had been done in Paris. During the War of the Rebellion he served as a medical officer in the Confederate Army, and after the war he was an associate editor of the *Charleston Medical Journal*. The Charleston *News and Courier* says of him: "He was a physician of high attainments, a teacher of rare ability, a scholar of great versatility, a writer of eminent merit, and a charming gentleman of the old school who, while alive to the demands of the crowding present, was not unmindful of the historic past. He will be missed in professional walks, and in the quieter and sweeter ways of society there will be many to long for the sight of the vanished hand and the sound of the voice that is still."

Death of Dr. Elijah S. Elder, of Indianapolis, Ind.—Dr. Elder, business manager of the *Indiana Medical Journal*, president elect of the State Medical Society, and for fourteen years its secretary, died at his home in Indianapolis, on May 19th. Dr. Elder was born at Dillsborough, Ind., on March 17, 1841. His father, Samuel Elder, was a physician. He came of good old revolutionary stock. Moving to Mount Auburn, Ind., he received his elementary education there, gained a teacher's certificate, and for two years taught in the Shelby County schools. For two years he was in mercantile life, and then, in 1863, became United States provost marshal for Shelby County and assistant marshal for the Sixth District. These positions he held till the close of the war. He was graduated from the Medical College of Ohio in 1867 and entered, practice at Morristown, Ind. He went to New York in 1875, and was graduated from Bellevue Hospital Medical College in 1876.

Dr. William G. Austin, one of the oldest and most eminent physicians in the South, died June 12 in New Orleans. He was born eighty years ago in Loudoun County, Va. He was Superintendent of the Charity Hospital in New Orleans before the war, and served in the Medical Department of the Confederacy. He returned in time to contend with the terrible yellow fever epidemics of 1867 and 1868.

Dr. E. L. Cocks, and not Cocker, was the gentleman elected as one of the officers of the Harlem Medical Association of New York.

The Academy of Medicine has appointed a committee of three, consisting of Drs. Daniel Lewis, George Henry Fox, and S. T. Armstrong, all Fellows of the Institution, to confer with the coming Constitutional Convention now in session, in regard to any such changes in the constitution as may be necessary to protect medical interests, and, through medical interests, those of the State.

Dr. Theophilus Parvin has been elected an honorary member of the Obstetrical and Gynecological Society of Berlin.

Society Reports.

American Medical Association.

Forty fifth Annual Meeting, held in San Francisco, Cal., June 5, 6, 7, and 8, 1894.

(Continued from p. 760.)

SECTION ON PRACTICE OF MEDICINE.

FIRST DAY, TUESDAY, JUNE 5TH.

The Structure of Blood-corpuscles and its Relation to Practical Medicine.—DR. J. H. WYTHE, of Oakland, Cal., read a paper with this title. From the earliest times physicians had recognized the importance of studying the blood; but owing to inadequate means it has only been within the past ten or fifteen years that a systematic study could be undertaken. The microscope has brought to the aid of the physician a means whereby a more careful and effectual study of the blood is afforded, especially the improved objectives, oculars, and other microscopical appurtenances.

The author emphasized the fact that testimony given as regards the particular animal from whence came a given specimen of blood was valueless, as the blood-corpuscles, even in the same animal and species, varied in size. Dr. Wythe pointed out that the blood is not simply an aggregation of corpuscular elements, but that the plasma is capable of exerting powerful influences on the economy. This he referred to as particularly noticeable as regards its bacteriacidal powers, as already established by American and foreign investigators. He believes this power to be due to the solvent action of the serum. Changes in the specific gravity as well as in the acidity and alkalescence of the blood should be noted—these often pointing to diseased conditions, and due probably to the absorption of certain toxines, ptomaïnes, or leucomaines, etc.

The structural changes occurring in the cellular elements of the blood, as a result of morbid process, has been extensively investigated by Ehrlich. In a number of observations made by the speaker, he said varied changes occur in the red blood corpuscles, when closely observed for a length of time and by the aid of the most modern instruments. The information thus gained conveyed to his mind the impression that the changes had a definite relation to diseased conditions. Furthermore, when we consider the various functions performed by the blood, it is not strange that we should have a variety of structure in its cellular components.

In conclusion, and as a plea for more thorough investigation of blood states, the speaker cited eighteen cases of beriberi, in which the blood of the affected persons was sent him for examination. In all cases he found the red corpuscles in various stages of disintegration. Basing his therapy on the observed facts under the microscope, he advised the use of ferrum, quinine, and generous diet, with the result that every case improved.

Digitalis in the Treatment of Pneumonia.—DR. WILLIAM WATT KERR, of San Francisco, outlined briefly the three principal classes of teaching as regards the use of digitalis in pneumonia. He said the first class regarded it as a specific; the second say it has little or no effect; the third believe its use is inadmissible on theoretical grounds—objecting on the ground that the congestion and consolidation of the lungs offer a great resistance to the pulmonary venous flow, this overcrowding the right heart, and that by using digitalis there is danger of inducing cardiac paralysis. The speaker claimed that digitalis increases cardiac systole, by stimulation of the heart musculature and the inter cardiac ganglia, and raises blood pressure. Further, it stimulates the vagi, thus prolonging diastole. Depressed cardiac action in pneumonia is due to: 1. Absorption of toxines and products of tissue-waste. 2. The pyrexia. 3. Obstruction to the circulation through the lungs.

Recognition of all the causes leading to depressed cardiac action is important. Prolongation of ventricular diastole is important: it gives the heart rest. The speaker never found digitalis produce any but good results when the indications pointed to its use. There are two conditions contra indicating its use: 1, When pneumonia occurs in patients with fatty or degenerated heart; 2, when the patient is extremely plethoric. Here he uses nitroglycerine to overcome arterial tension.

Digitalis is beneficial in certain cases of pneumonia, but no claim is laid for its being a specific. So long as the heart is doing its work well it should be left to itself and the course of treatment directed to the other morbid conditions; but just as soon as there is evidence of cardiac weakness, give digitalis, ℥xv., every three hours, till the pulse shows evidence of the effect; then reduce dose sufficient to hold heart steady. When a patient comes under observation, after the heart is overcrowded, the speaker believes the best line of treatment is blood-letting and digitalis.

Tincture aconite and tincture veratrum viride are more harmful than good. Digitalis frequently fails in the treatment of pneumonia, because its action is essentially on the nervous system, and this is overcome by the pyrexia and toxæmia; hence this should be overcome by the use of strychnine, etc. In closing, the speaker urged a more competent and thorough study of the pulse, it being the great indicator of the drug action of digitalis.

DR. WASHINGTON AYER, of San Francisco, called particular attention to Professor Kerr's approval of venesection. He believed the lancet a most excellent agent, but requiring caution in its use. When the pulse is feeble, secretions thick, tenacious, and viscid, respiration very difficult, and the patient appears to be in articulo mortis, venesection is the only thing that offers any hope of relief.

Digitalis should not be used without proper consideration. We ought to return again to the much-abused lancet in the severe and dangerous forms of pneumonia.

DR. DEWITT, of San Francisco, stated that his personal experience shows ℥xv. per dose of tr. digitalis too much. He has found a "reflex action" occur, making him fearful of the dosage; and further, with such large doses, he always found nausea followed.

DR. YOUNG, of Tahoe, was glad of the tribute paid by Professor Kerr to the ense of touch as possessed by the older practitioners. He would not use such large dose as suggested by Dr. Kerr.

DR. HURST, of Indiana, cited two cases in his early practice where digitalis was being given in ʒj. doses of the infusion. One case presented a pulse of forty per minute, profuse sweat and nausea, when the speaker was called in. He stopped the digitalis, gave whiskey and general stimulating treatment, and saved his patient. The other case ended fatally, and, in the opinion of the speaker, because of too much digitalis injudiciously used. He believed that gtt. v –viij. of the tincture was as much as could be given at one dose without inducing nausea. He further endorsed the use of the lancet in many cases.

DR. E W. KELLOGG, of Milwaukee, stated that he considered tincture digitalis unreliable.

DR. LOVING, of Chico, endorsed digitalis, but found that, as a rule, not more than one or two doses of ℥ xv. could be tolerated. He usually used only ℥ viij. per dose, and found nausea occurred almost uniformly under larger dosage.

DR. HOLDEN, of Vermont, called attention to the action of digitalis on the nerve centres. When first administered there results an intermission of the pulse. This shows a slowing of the heart. Large doses of digitalis is "whipping up a horse going as hard as he can" in its action on the heart. Digitalis should be used only when there is a weakened heart action, and as a source of strength: further, it should be combined with nitroglycerine, to keep the blood in the extremities. In some cases venesection is of undoubted service.

DR. JENKINS, of Iowa, remarked that there is nothing

better than digitalis and nitroglycerine at about the crisis, and in addition plenty of whiskey. This line of treatment is particularly good in asthenic cases.

Dr. Ayer, of San Francisco, uses whiskey and ammonium carbonate when the heart becomes weak. Use diligently and fearlessly is his advice. Unless some stimulation is resorted to there is liable to be venous stasis in the lungs.

Dr. Kerr, in closing, said that the dosage of ℥xv. digitalis referred to the U S. P. tincture, and he again emphasized the fact that this dose was to be diminished as soon as the pulse showed the drug action. He had rarely had any nausea result in patients suffering with croupous pneumonia, although he had observed nausea result from digitalis in some heart cases. The speaker does not advocate the indiscriminate use of digitalis in pneumonia, but in those cases indicating its use there is always benefit. He condemns modern cheap text-books that give the routine treatment for various diseases, without a proper consideration of the indications for drugs.

Leprosy in San Francisco.—Dr. Douglass W. Montgomery, of San Francisco, presented a paper which was read by the secretary, Dr. Pierson. The author took the ground that leprosy was a contagious disease, proved by clinical evidence, and such being the case, care should be taken by all municipal authorities to isolate those suffering with the disease. Dr. Montgomery took the Chinese quarter of San Francisco as an example of a favorable soil for the growth of leprosy.

He cited a number of cases that had come under his observation, in the persons of Chinese, that would seem to show the disease was contracted in this country; but a more careful investigation of the history showed, in every instance, it was probably contracted in China. The author stated he had never met with a leprous Chinese native of this country.

The period of incubation, from the cited cases, was very variable.

Importance of Early Diagnosis and Prompt Treatment in Acute Catarrhal Pneumonia.—Dr. W. R. Cleaveland, of Biggs, Cal., said that careful physical examination of the chest should be made especially in the old and in the debilitated subjects in whom there was a suspicion of pneumonia. This will often serve to avoid a catarrhal pneumonia. Percussion will clear up the diagnosis between catarrhal and croupous pneumonia. Auscultation will first give warning of the impending trouble. The earlier free expectoration can be brought about, the better the chances of the patient.

In the experience of the speaker many cases follow la grippe, and the majority of cases of catarrhal pneumonia occurred in strong and robust individuals. Treatment includes the application of a jacket of surgeon's lint, covered with oiled silk or mackintosh, the internal use of ammonium carbonate and ammonium iodide as expectorants. Air of the room should not be dry, but kept moist with an atmosphere of ol. eucalyptus and ol. terebinthin.

Strychnia should be used, also quinine, in tonic or stimulating doses. Alcohol, in form of whiskey, as eggnog, is of utmost service; in fact, alcohol in some form must be used. For the febrile symptoms acetanilide or phenacetin may be used. Apomorphine is an important and most excellent expectorant. Cases taken early, free expectoration being established, the digestive apparatus attended to, and we are in a position to look for favorable results.

Digitalis and trinitrin may be used in cases with weak heart. Vesicants should be used to hasten absorption of consolidated areas, giving internally, syr. acid. hydriodic. and syr. hypophosphites of lime and soda.

Second Day, Wednesday, June 6th.

The Influence of Atmospheric Pressure upon the Prevalence of Pneumonia.—Dr. C. M. Richter, of San Francisco, presented a careful study of the influences of atmospheric pressure in pulmonary disease. He claimed that pneumonia presents no evidence of having a bacillary origin, and that even in well-marked cases the specific germ is rarely found.

There are several forms of pneumonia: Epidemics generally affect children under five years of age, and adults over fifty years of age, in greater proportion.

The liability to pneumonia begins with zero at the poles, and gradually increases to a point in the temperate zone, here again diminishing toward the equator. Winter and early spring show the greatest proportion of cases; summer and early autumn the least. This, according to the speaker, may be explained by the greater maximum atmospheric pressure during the months when pneumonia is prevalent, or, summing up, the greater the continued maximum high atmospheric pressure, the greater the occurrence and mortality of pneumonia. Statistics were given, covering a number of years, and including the large cities of Europe, America, and Australia, which went to bear out the speaker. However, in closing he urged a more extensive and thorough line of research with the view of finding the effect of continuous, or extreme, high atmospheric pressure on the organism.

Dr. A. W. Perry, of San Francisco, said he did not believe that high pressure was a causal agent of pneumonia, giving as his reasons the following:

Pneumonia is common in the mountain towns of California. Is it more prevalent or more fatal because of the high barometric pressure? From information gained in talking with confrères practising in these towns, he thought not. Further, he would like Dr. Richter to state if he meant that pneumonia was caused by high or low barometric pressure; by the oscillations, or by bursts of pressure.

Dr. Richter, in closing, said that from his statistics pneumonia was not more prevalent in the mountainous districts than in valley towns and cities. It is not the oscillations of pressure, but the maximum continued high pressure he referred to.

Dr. Kellogg, of Milwaukee, wanted to know if the statistics given by Dr. Richter were made from deaths or all reported cases.

Dr. Richter replied that the statistics were derived from deaths only, there being no means of getting the actual number of cases.

The Relations of Micro organisms to Fever.—Dr. Washington Ayer, of San Francisco, read the paper, in which he assumed a negative position as to the germ theory—stating that he considered some conservatism necessary in this day of bacteriology. He said fever is an important factor in almost every disease. In its generic sense fever means an exalted temperature of the blood as a result of increased tissue destruction. Mutation and nutrition are interrupted.

He called attention to the fact that even the same type of fever shows great variations in different patients, and even in the same individual. From this he concluded that if germs were the materies morbi there would be more uniformity. Does convalescence show that the germs have ceased to proliferate, or that they are afraid of the fusillade of remedies fired into their camps?

Typhoid is generally milder in course on the Pacific slope than on the Eastern coast, and yet the causa belli is claimed as one and the same. Why? In the opinion of Dr. Ayer, one example, viz., intermittent fever, makes the germ theory for fevers untenable. In concluding the speaker said, more careful work in practical medicine and less in the dreamland of microscopy was needed. At present all the investigations have only proved the existence of organisms.

Dr. W. N. Miller, of Pennsylvania, believed in micro-organisms to a certain extent, but thought practical medicine and conservative judgment were needed in conjunction.

Tubercular Peritonitis.—Dr. McNutt, of San Francisco, presented the reports of four cases upon which he had performed cœliotomy for primary tubercular peritonitis.

In all these cases complete recovery took place, and has been permanent. He emphasized the point, that from his investigations all these cases were primary, no evidences of a tubercular process in other organs being found. In all four cases the peritoneum was found thickened, covered with thousands of miliary tubercles, and in the cavity an exudation, varying in character in the different cases. Microscopical examination of a piece of the peritoneum, the site of tubercles, made by Dr. Montgomery, of San Francisco, showed the histological elements to be those of tubercles, although no tubercle bacilli could be detected; however, the macroscopical and microscopical appearance was distinctly tubercular. One other point dwelt upon by the speaker was the peculiar shape of the abdomen noted in cases of tubercular peritonitis with effusion. It resembles that found and due to cystic disease, and not as is generally found in ascites. This Dr. McNutt attributes to the fact that the effusion occurs into the thickened peritoneal wall.

Dr. J. F. Carpenter, of Pennsylvania, would like to know if drainage, when employed, was from the most dependent part, through and through, and was any medicine employed?

Dr. McNutt said that ordinary abdominal drainage required no medication.

The Pathology of Tetany.—Dr. John F. Carpenter, of Pottsville, Pa., said that from recent contributions made to the pathology of tetany it is now recognized as a nervous disease. No post mortem changes have been found to show the exact nature of the disease. A second cause of pathological uncertainty lies in the fact that the disease occurs in various forms, viz.: 1, Rheumatic; acute or epidemic tetany; generally fatal. 2. Chronic, due to chronic diarrhœa, prolonged lactation, etc.; recovery usual. 3. Occurring in the course of dilatation of the stomach. 4. Surgical tetany, following removal of thyroid gland especially; generally fatal.

Tetany is found to follow such diseases as produce a morbid discharge from mucous surfaces, and due to sepsis.

This is especially true of the puerperium, when complicated by septic infection. The speaker, in summing up, said that, in his opinion, sepsis is clearly traceable as the causal agent of tetany. In all the conditions predisposing to its occurrence septic infection is clearly probable. Furthermore, sepsis and septic absorption will account for other grave nervous disorders, this being due to the fact that blood-poisoning by septic material causes a profound anæmia, this being the proximate cause of nervous irritation. Several cases occurring in the practice of Dr. Carpenter were cited to prove his views. Habit also has an influence. He found attacks of tetany kept up owing to an unstable equilibrium, which was set up by the original attack. At the present time, thanks to antiseptic precautions, tetany is but little known, and the speaker expressed the belief that in the near future it would be wholly a disease of the past.

(To be continued.)

Disposition of Professional Tools and Records.—A correspondent writes: "Sir: Can anyone tell what becomes of the instruments, office furniture, diplomas, and case-records of deceased physicians?"

The Reconqueror of Algiers.—After the conquest of Algiers by the French, during the period from 1834 to 1840, a very fatal disease of unknown nature decimated the army of occupation. A young military surgeon, named Maillot, set himself to study the scourge, and came to the conclusion that it was malarial in origin. He instituted the treatment by large doses of quinine, and the mortality fell at once from twenty-five to five per cent. In the very first year, this medication saved 1,437 lives in one hospital. What a triumph for clinical medicine! We may well say that the illustrious Maillot reconquered Algiers for France.—Huchard.

Congress of American Physicians and Surgeons.

Third Triennial Meeting, held at Washington, D. C., May 29, 30, 31, and June 1, 1894.

(Continued from page 7[illegible].)

AMERICAN SURGICAL ASSOCIATION.

Fifteenth Annual Meeting, held at Washington, D. C., May 29, 30, 31, and June 1, 1894.

Second Day, Wednesday, May 30th.

Methods of Teaching Surgery was the title of a paper by Dr. John S. Billings, of Washington, D. C. We have to consider, Who are to be taught? What is to be taught? How is it to be taught?

Who are taught?—Those to be taught are the average medical student and those wishing to specially fit themselves for surgical work.

What is taught?—The instruction to the average student should in all cases include the diagnosis and best methods of treatment, together with the selection and administration of anæsthetics. Is it worth while to go into the details of cerebral and abdominal surgery, excision of organs, and kindred operations? Is it not enough to tell the average student what can be done in these directions, and refer him to special courses for further information?

How are these subjects to be taught?—There are five principal methods: Didactic systematic lectures; recitations; demonstrations; theoretical clinical lectures; and practical clinical instruction to small groups.

In old-time schools the professor of surgery taught surgical pathology, or the principles of surgery and surgical anatomy. He was the clinical as well as the systematic teacher, and the student was not bewildered with the conflicting views of different professors as is the case in the present day. How the subject of surgery can be subdivided among the several professors of surgery without involving useless repetitions and embarrassing contradictions is one of the most difficult problems in the organization of a large medical school.

Theoretically, every professor desires only the best interests of his pupils and of his school, and there are frequent consultations to secure harmony in their teachings.

Practically, there are usually two or three strong-minded men in the faculty who settle what shall be done, and the rest find it expedient to submit, although they may not agree.

As regards the teaching of surgical anatomy and operations upon the cadaver, by a teacher distinct from, and entirely independent of, the professor of surgery on the one hand, and the professor of anatomy on the other, there are widely different opinions as to its expediency.

Might it not be best that the attendance on such an independent course be purely voluntary on the part of the class?

Didactic and Clinical Instruction.—As a rule, clinical material is not available to cover the entire field for any school, no matter how large its hospitals and dispensaries; hence, there mus tbe some systematic didactic teaching. Is it best that this should be a complete independent course covering the whole field, merely using for any particular subject such cases as may happen on that day to be available?

On the other hand, there are certain advantages in deferring the systematic lectures until toward the end of the course, and then devoting them mainly to subjects which had not been illustrated in previous clinical teaching; but to make this plan a success it would be necessary that the systematic lecturer have given all, or be familiar with all, clinical instruction that had been given.

What are the Advantages in the Present Mode of Clini-

cal Instruction?—How much does it profit the student to witness from the rear benches of an amphitheatre such operations as may be performed? It seems to me two hundred men cannot possibly obtain any special information from surgical clinics in an amphitheatre, which they could not obtain equally well in a didactic lecture, or with illustrations by means of lantern slides.

With regard to allowing students to treat or operate upon the patients in the hospital, the patients would naturally object and avoid such hospitals.

Recitations and Quizzes.—These are excellent methods for the majority of students, but are only well adapted to small classes or sections. These are at present mainly conducted by private individuals, but if made part of the official course and applied especially to clinical teaching, one good result of this would be to discourage the reliance on quiz compends, which I think invariably do more harm than good.

Modes of Lecturing should be definite, selective, and to a considerable extent dogmatic. What the student sees and hears during the first half hour of the lecture is what he remembers best. Therefore, let the teacher describe the method which he prefers, first. If the reasoning is given before the conclusions are stated, the student is apt to get confused.

If the lecturer will fix in his mind the half-dozen questions he would test the students' knowledge of the subject upon which he is going to speak, and answer those questions clearly, definitely, and fully, he can hardly fail to give a good lecture. Too much history of medicine and surgery should be avoided. Students wishing to fit themselves especially for surgeons should make a special study of surgical anatomy, practical laboratory work in bacteriology, pathological histology, and experimental pathology and physiology.

Use of Animals for Instruction.—Much of the operating technique can be learned on animals, but much of it also requires work upon the cadaver.

Also, would it not be well that the first dissections be made on cats and dogs until a good technique has been acquired, so that the supply of cadavers, which is always insufficient, can be fully utilized to the best advantage? I also think it unwise to have the final examination in anatomy one or two years before the other final examinations; the anatomy should be kept up throughout.

Residence in Hospitals.—This is most important of all, the working as assistant to a surgeon, the seeing and handling cases, and not merely looking at them from a distance.

Finally, are there not some subjects which occupy too much space in the undergraduate curriculum, such, for example, as inorganic chemistry and embryology?

Limiting the Number of Pupils.—If our first-class popular medical schools would fix a limit to the number of students which they would receive either in the first or in the third year, or in both, and enforce this limit by competitive examination or by higher fees, or by both, it would bring the best men to them, and would enable them to do thoroughly good work.

Dr. Warren, of Boston, thought what was first needed was a thorough preparatory education of the student before entering the medical school. He would only admit students having the A.B. degree, so that by spending four years in an academy, four in a medical school, one in the hospital, and one year abroad to finish his studies, it would make ten years in all. He thought during the first year there should be little or no work done in surgery, and the student should be excluded from clinics. During the second year he should have exercises in bandaging and experimental work upon animals, together with the application of sutures, dressings, etc. During the third year he should get as much clinical teaching as possible, but systematic didactic teaching should not be discarded entirely.

Dr. Keen, of Philadelphia, was strongly in favor of thorough instruction in anatomy and dissection of the lower animals, which could be killed when wanted and thus provide fresh tissues, which are wholly unlike those of the cadaver subjected to post mortem changes for perhaps months. The tissues of the cadaver greatly differ from those with which the surgeon has to deal. First-year students should not be allowed to attend clinics. Clinical work will never replace the didactic work. What are text-books to the voice? Recitation work should count upon the final examination. The student also wants only your exact views, and wishes to leave the lecture room with clear ideas.

Dr. Warren further added that in the didactic work all kinds of fractures could be shown which would be impossible to show in the amphitheatre. All students should be taught practically how to administer anæsthetics, and the coming college must have a hospital of its own.

Dr. Connor, of Cincinnati, claimed that it would be unjust to insist upon all students to first be in possession of the B.A. degree and then possibly have to practise at some country cross-road where the people around him were unable to speak a single sentence correctly.

Dr. Forbes, of Philadelphia, thought the students of to day were given more work than they were capable of doing, and it caused mental indigestion.

Dr. Weir, of New York, said in the college with which he was connected the students of the first year have nothing to do with clinical work. In the second year there is a small amount of practical work, such as bandaging, etc. In the third year the work was principally didactic, while the fourth was almost entirely composed of practical instruction.

Dr. Prewitt, of St. Louis, agreed with Dr. Connor that it was impossible and uncalled for, that all students should have the degree of A.M. or B.A. If a man is a good English scholar, why should he know Latin and Greek?

The paper was further discussed by Drs. Nancrede, of Ann Arbor; Owen, of Chicago; and J. E. Mears. A paper from Dr. Chene, of Edinburgh, was also read as part of the discussion.

The Surgery of the Kidney was the title of a paper read by Dr. L. M. Tiffany, of Baltimore. He said that bi-lateral organs were more than sufficient to carry on the functions of the body, but to what extent the kidneys may be impaired and still work is uncertain. The amount of urine passed and the solids it contains would best answer the question. In every case examined after injury during the past six months, albumin was present. In a few cases casts were found, but in the majority they were absent. After accidents, the amount of urine in all cases was extremely small for the twenty four hours. The amount of urine passed is a better indication of the patient's ability to stand an operation than the albumin or casts. In almost all cases the nephritis has been an ascending one. I believe a low temperature with a moderate amount of urine is more important than anything else; especially is this the case with a very low temperature.

Diagnosing which Kidney is Affected.—Here the cystoscope will be of great use in the future, but at present I rely upon digital examination. Acid urine with pus points strongly toward infection of the kidney.

Treatment before Operation.—Increase the amount of urine, and get the temperature normal. After the operation, strychnine has proved more valuable than anything else.

Suppurative Nephritis.—The pain is often absent from kidney and located elsewhere, in the side, and even in the bladder.

Wounds of Kidney should be treated as a wound elsewhere. The kidney should be explored from behind, and uncovered as much as necessary. It should be sutured, tamponed as any other organ. Unless the kidney is greatly disorganized, nephrectomy is uncalled for. It should be treated as any other portion of the body, *i.e.*, remove only as much of it as its condition calls for.

ASSOCIATION OF AMERICAN PHYSICIANS.

Ninth Annual Meeting, held in Washington, D.C., May 29, 30, 31, and June 1, 1894.

Third Day, May 31, 1894.

Tetany in America.—Dr. J. P. C. Griffith, of Philadelphia, reported five cases of tetany of varying types, some of them continuous, approaching or including the carpo pedal spasms of some authors; some of them paroxysmal in nature. The cases show that those authors are probably correct who include all these forms under one general heading, "Tetany." All gradations seem to exist between the mildest and the severest cases. Certainly, in the present state of our knowledge, we are unable to make any sharp distinctions.

Considerable confusion exists as to the characters of the disease. Many forms have been described, but in this country very few cases had been reported. One is surprised at the paucity of American records, as he had only been able to collect seventy two cases. The definite cause of the disease is not known, nor is it possible to locate its pathological seat in any part of the body.

Up to the present time the only treatment had been by sedatives. The relative rarity of the disease in this country may be inferred from the infrequency of laryngismus stridulus, which is undoubtedly an allied condition.

Leucocytosis in Febrile Conditions.—Dr. F. P. Kinnicutt, of New York, presented charts showing studies in the amount of leucocytosis in febrile diseases, as observed in cases at St. Luke's Hospital. There was no discussion

Lead Palsy in Children.—Dr. Wharton Sinkler, of Philadelphia, read the paper. Lead palsy in children is a rare disease, although there is no apparent reason why children should not be affected as readily as adults. But few cases of this kind can be found in literature.

Lead palsy in children very closely resembles polio myelitis anterior, and is probably often mistaken for this disease; and this may account for the small number of cases of lead palsy in children which have been recorded. The rarity of the disease in children might be because lead is eliminated so easily by them. Even in adults susceptibility varies very much. In children poisoned by lead sensory disturbances are rare, but cerebral symptoms common; lead encephalopathy is more common than in adults. The author reported cases of three children in one family suffering from this affection, the disease being traceable to white lead for painting, which was kept in the house. He had only been able to find eight cases in literature. In children the distribution of lead palsy differed from adults in that the legs were equally liable to paralysis with the arms.

Dr. J. J. Putnam, of Boston, referred to experiments upon dogs which showed in them that the spinal cord participated somewhat in the pathology of the disease.

Dr. A. Jacoby, of New York, had seen two cases in which the arms and legs were equally affected.

Dr. M. A. Starr, of New York, reported two cases in children. One was fatal, and autopsy showed an absolutely normal cord, but neuritis, most marked toward the extremities.

A Study of the Temperature in Cerebral Apoplexy.—Dr. C. L. Dana, of New York, discussed the effect of cerebral hemorrhage and acute softenings upon: 1. The general bodily temperature. 2. In causing unilateral rise. 3. The comparative effect of the two processes in causing temperature disturbance. 4 The question of the localization of lesion in reference to temperature.

He endeavored to show that hemorrhages cause elevation of temperature, and more on the affected side. That softenings do not cause such elevation; that all apoplectic temperatures are low and have no diurnal variations; that temperatures above 103° F. are evidence of complications (pneumonia). That lesions of the thalamus may cause a high temperature. That a close study of temperature helps greatly in diagnosis and prognosis of the apoplexy.

In fatal cases the temperature averaged 101° F. The general law is that temperature rises after severe hemorrhagic laceration of the brain, but not after embolic processes. The axillary temperature on the paralyzed side averaged one degree higher than on the healthy side. The localization of a heat centre in the brain had not been much assisted by pathological observations. Fever depends more upon the amount of laceration than its locality. Discussion by Drs. J. J. Putnam, of Boston, and Dr. C. G. Stockton, of Buffalo.

The Mild Character and Diminished Prevalence of Syphilis, and the Infrequency of Visceral Syphilis.—Dr. J. H. Musser, of Philadelphia, wished to prove that syphilis of the present day is of mild type, and is infrequent as compared to a period of twenty years ago. He discussed the questions whether it is, 1, because the community is becoming immune; 2, because the virus is less active; or 3, because of the change in the habits of cleanliness of the public. When the infrequency of visceral syphilis is considered, and the fact that syphilitic disease of the lungs, liver, and kidneys is extremely rare, are we warranted in the belief, therefore, that this infection is the cause of so-called nervous syphilis or of nervous diseases due to syphilis?

The author acknowledged that definite statistics were not available, but from his studies of the records of the Philadelphia Hospital he believed that the percentage of cases was one-half that of twenty years ago, and of a less malignant type.

Dr. E. G. Janeway, of New York, said it would be a mistake if we overlooked syphilis as a factor in disease. Locomotor ataxia and general paralysis seem to be due to syphilis. He had seen four cases of visceral syphilis, one of which was mistaken for phthisis. Again, syphilis stands very strongly as an ætiological cause of aneurism.

Dr. H. M. Lyman, of Chicago, said that in the Hawaiian Islands the disease had at present assumed a much milder type than formerly. All great outbreaks of syphilis had been coincident with great movements of population.

Dr. I. E. Atkinson, of Baltimore, said that it is difficult to discuss a paper based upon statistics, but that his experience in Baltimore was directly contrary to that of the writer.

Dr. Post, of Boston, said that he was constantly seeing more and more and graver and graver cases of syphilis. He disagreed with the writer.

He said that, considering the lack of control of syphilis in the United States, it would be strange if the disease did diminish.

Some Remarks on the Significance of Albumin and Casts, Especially in those past Middle Life.—Dr. F. C. Shattuck, of Boston, read the paper. The frequency and the presence of albumin has been carefully studied; also the number and frequency of casts. Analysis of private and hospital patients during the past five years with reference to these points, seems to show that some traces of albumin, hyalin, and granular casts are the rule rather than the exception after middle life, and that their prognostic import is often trifling.

The presence of albumin and casts formerly meant Bright's disease, and the presence of a fatal disease was predicated. This view has now been much modified.

The best clinical test for albumin is nitric acid and heat. Casts should be carefully looked for. The author is always sceptical when albumin (of renal origin) is reported without formed elements and casts. Casts of small diameter, hyalin or slightly granular, are extremely common.

He had found albumin and casts in a large percentage of non-nephritic patients, which percentage increased rapidly with age. The pathological significance is difficult to follow. It is probably due to senile changes.

Dr. I. N. Danforth, of Chicago, had long ago come to regard transitory albuminuria as of little import. He

considered the study of the character of casts of much importance.

Experimental Phthisis in the Rabbit, with Formation of Cavities; a Demonstration.—Dr. T. M. Prudden, of New York, showed a large number of the lungs of rabbits which had been the subjects of intra-pulmonary injections of bacteria. The lesions closely resembled those seen in man. He had studied the effect of the streptococcus and of the tubercle bacillus, and then the results of the two together. An informal discussion of the specimens, which had excited much interest, followed. The existence of cavities in rabbit pulmonary tuberculosis had been denied by many experimenters.

Cough, Aggravated by Horizontal Posture on one Side, as a Strongly Suggestive Symptom of Unilateral Tuberculosis.—Dr Norman Bridge, of Los Angeles, Cal., said that in early phthisis the cough may be produced by lying on the affected side. Later the disease invades the other lung, and then the phenomenon is reversed. When the position of the patient is such that secretions gravitate toward the smaller bronchi, cough is excited; when they flow toward the trachea no cough may be produced. No discussion.

A Report of the Ultimate Results Obtained in Experimental Eye Tuberculosis by Tuberculin Treatment and Anti-tubercular Inoculation.—Dr. G. L. Trudeau, of Saranac Lake, N. Y., sent a paper which was read by Dr. Loomis. In the great majority of cases the tubercular process, which has been apparently cured in the rabbit's eye by tuberculin treatment, slowly relapses. This tendency to relapse may show itself as soon as the injections are no longer capable of producing reaction in the eye, or an apparent cure having taken place. The process may remain arrested and the eyes well for months before the tendency to relapse manifests itself. The inhibitory influence exercised by the treatment on the more chronic forms of this type of tuberculosis seems demonstrated, though in most cases only temporary.

Protective inoculation by means of graded doses of living avian bacilli, gives results more satisfactory, and which seem more permanent. Relapses, it is true, do occur in a fair majority of cases, but, even on these, the inhibitory influence of the preventive treatment is manifest. In some the disease runs a chronic course, and, even when the eyes are ultimately entirely destroyed, this does not occur until many months after it has taken place in the controls. In other of the relapsing cases the inhibitory influence of the preventive inoculation is frequently so marked that the disease progresses almost imperceptibly, and is characterized by long periods of complete arrest. In a fair proportion of animals, however, the eyes recover completely from the tubercular inoculation, and the degree of persistence of this apparent immunity is shown by the fact that inoculation, six months later in the sound eye, may follow the same typical course as in the first instance, and the second eye, also, be completely restored.

Though dangerous to the animal's life, and uncertain in its protective effects, a study of anti-tubercular inoculation indicates that the reaction of living tissues to tubercular inoculation can be modified artificially, and thus the production of a relative, and in a few cases an apparently complete, artificial immunity is a possibility.

Photographs illustrating these points, and taken a year after the virulent inoculation, were shown with the paper.

(To be Continued.)

Yellow Fever was imported into Brazil, says Dr. Bulhoes Carvalho, in the *Brazil-Medico*, from New Orleans, in 1849, the first cases seen in Rio de Janeiro being in 1850.

Methyl Mercaptan is the substance to which the peculiar odor of the urine after asparagus has been eaten is due. It was isolated by Nercki.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 17, 1894.

D. B. St. John Roosa, M.D., President, in the Chair.

The Nature and Management of Functional Gastric Disturbances.—Dr. Charles G. Stockton, of Buffalo, N. Y., read the first paper. Functional gastric disorder, he said, was very rarely primary. In reviewing a series of five hundred cases, seen since the beginning of 1893, and of which he had made a careful study, in not a single one could it be said that the functional gastric disturbance lay primarily in the stomach. This, however, did not impeach the possibility of such an occurrence. While it was readily conceivable that an overtaxed stomach alone might give rise to a gastric neurosis, yet in point of fact one rarely found gluttony the essential cause. Something had gone before or accompanied the over-indulgence. It was remarkable how many insults the stomach would tolerate, and if a subacute gastritis resulted it would subside under the rest attending a diminished appetite, so that no permanent trouble followed.

What, then, were the influences which invited persistent functional disorders of the stomach, was a question which should arise in the physician's mind whenever a case presented itself. The stomach, like a mirror, reflected almost every influence to which the human organism was subjected. Irritation of the brain, cord, kidneys, uterus, and of various other organs, might lead to anorexia or vomiting. One had not far to go for an explanation of this fact, as scarcely any portion of the system had so complex a sympathetic nerve supply as the stomach. If the stomach contents were examined under these conditions, no evidence would be found of subacute gastritis, no ropy mucus which inexperienced men wrote so much about; but evidence would be found of serious derangement in gastric innervation, exhibiting itself under some slight excitement, some depression, etc. While there might be some deficiency of hydrochloric acid or evidence of a defective state of the peptic glands, yet the physician must not rest satisfied with discovery of this fact and prescribe a drug simply for immediate and temporary relief, but should look further and find, if possible, the reason for the nervous energy being diverted from its ordinary course. One should look for central or peripheral nerve irritation, or toxæmia. The nerve irritation might be due to structural or functional disease, perhaps mental strain, or some defect in organs of special sense, particularly the eye. Among spinal cord affections which might give rise to functional gastric disturbance were lordosis, tabes, hysterical spine, etc. Kelly and Mann had called attention to ureteritis as a cause of reflex gastric troubles.

Dr. Stockton then took up the influence of toxæmia in the production of functional gastric disturbances, mentioning functional or organic inadequacy of the kidneys, alcohol, tobacco, malaria, gout, some of which doubtless acted through the medium of the blood. Syphilis had been a cause in a few of his cases, as shown by the history and response to anti-syphilitic treatment.

In regard to the question whether given irritations, especially reflex and toxic, would produce distinct varieties of gastric neurosis, the answer must be that in the main they would not. In his experience gastric neurosis was not likely to be due to organic lesions of the stomach.

Successful management included correction of the diet and removal of the cause where this could be discovered.

To recapitulate: It was held, 1, that functional gastric disorders generally arose from influences outside the stomach; 2, these causes were to be easily found in some reflex irritation or toxæmia; 3, among the toxæmic causes syphilis was occasionally found; 4, structural changes in the stomach were not so much the causes, as they were the result, of functional disorders; 5, treatment to be successful must include removal of the exciting cause.

Clinical Observations on Erosions of the Stomach and their Treatment.—Dr. Max Einhorn read the second paper (see p. 780).

Dr Kinnicutt regretted that he had been unavoidably absent during the reading of Dr. Stockton's paper.

Dr. Einhorn's observations were novel ones to him, and deserved more extended study. He not infrequently had detected shreds, and occasionally even pieces, of gastric mucous membrane, as large as those described by Dr. Einhorn, in the washings from the stomach; the latter only when aspiration had been employed. He could say, however, that he had never seen appreciable evil follow. He had believed that these bits of mucous membrane were the result of injury done by the tube. The spraying of the gastric mucous membrane in the manner described by Dr. Einhorn, certainly was most ingenious, and it seemed to him might be of much practical aid in various morbid conditions.

Dr. Einhorn had been led to believe that a very rapid healing of what, from his description, must represent a serious lesion of the gastric mucosa, followed the particular medication which he had described.

From anatomical considerations and from the clinical history of ulcers of the stomach, he thought that such an inference should be received with caution.

Dr. Northrup had seen nothing analogous to the exfoliation of the gastric lining membrane described by Dr. Einhorn, although he had now and then found some of the superficial stomach cells entangled in mucus. He could not understand how, unless there were traumatism, the lining membrane down to or including the submucosa, could be cast off in pieces or produce so little trouble.

Dr. J. Fuhs, of Brooklyn, remarking upon Dr. Stockton's paper, expressed the opinion that, while a variety of diseases affecting various organs might cause functional gastric disturbance, yet we were often unable to trace the relationship, and we were therefore compelled to do something for the cases aside from removing the first cause, as this was unknown to us. For instance, there might be hyperacidity; the cause being unknown, the indication for treatment was to neutralize the acidity. In another case the indication might be to overcome muscular spasm or paralysis. In one case the stomach was found to contain a large quantity of food an hour and a half after the meal; but on examination half an hour later, he was surprised to find the stomach empty. There was one organic condition which constantly gave rise to reflex gastric disorder, namely, disease of the pelvis of the kidneys. In a case related, discharge of pus from the pelvis of the kidneys was followed by relief of the stomach symptoms. The vomited matter in this case contained so much hydrochloric acid as to produce a burning sensation on the teeth. In certain biliary cases he found hyperacidity between the attacks, diminished acidity during the attacks.

Regarding Dr. Einhorn's paper, Dr. Fuhs said he had seen two cases which possibly might have belonged to the same category.

The President regretted the author of the first paper had not dwelt a little longer upon the question of functional disturbance of the stomach resulting from eye-strain, for the relationship to it had not been made perfectly clear to his mind. Almost everything had been attributed to some trouble in the eye, unless it were a fractured limb.

Some closing remarks were made by the readers of the papers.

Action on Amendments to the Constitution.—Amendments to the constitution having been proposed at the last meeting, to create two new standing committees whose chairmen were to be members of the council, a house committee and a committee on nurses, Dr. A. Jacobi desired that they be rejected; whereupon a warm discussion followed, taken part in by Drs. Jacobi, Gray, A. M. Jacobus, R. Van Santvoord, Hanks, the President, and others. There being antagonism between certain members of the council and the committee on nurses, the latter desired representation in the council, in order that misunderstandings might be avoided in the future; while on the other side it was argued that the council was already too large, being composed of fifteen members, and that the house committee and the committee on nurses were as yet only in the experimental stage. When the motion was put on the adoption of the proposed amendments, there were twenty four votes in the affirmative, seventeen in the negative. A three fourths majority being required to change the constitution, the motion was lost.

Against Reducing the Army Medical Corps.—Resolutions were adopted against the reduction of the Army Medical Corps, as proposed in Congress.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, March 2, 1894.

Charles L. Dana, M.D., President, in the Chair.

Notes on the External Use of Guaiacol and Creosote.—The President, Dr. Dana, related some experiments which he had made with the external use of guaiacol and creosote since December, 1893. The external use of guaiacol was first suggested, he believed, by Sciolla, of Italy, a little over a year ago, and subsequently by two French physicians, Robillard and Guinard, and reports upon its use had been made in this country by Dr. Solis-Cohen and Dr. Foster. It was shown that by rubbing twenty or thirty drops of guaiacol upon the skin a reduction of temperature took place, varying from two to five, or even more degrees. The temperature sank rather rapidly, remained down one or two hours, and gradually returned to its former level. The action was much like that of other antipyretics, except that one seldom noticed chills or cyanosis. Dr. Dana's house-physician at Bellevue Hospital, Dr. Farrington, had used guaiacol in a number of cases of disease with fever, and charts were exhibited, showing its effect in reducing the temperature. There were five cases of acute lobar pneumonia, one case of typhoid fever, one of phthisis, one of chronic bronchitis, one of acute miliary tuberculosis, and others. The charts showed that the action of the drug was very striking in some cases. It very rarely failed to produce the desired effect of reducing the temperature. In some the fall was only one or two degrees; in one it was nine degrees, down to 96° F.; in another Dr. Dana saw a fall from 105.5° to 99°. In one case there was a slight chill, but disagreeable effects were seldom seen.

It seemed to the speaker that the guaiacol had more effect in modifying the temperature about the beginning than toward the end of the acute fever. In pneumonia it seemed that rubbing the guaiacol on the skin about the fourth or fifth day hastened the crisis, and the crisis was less typical than usual. In two cases in particular, the crisis seemed to have been brought on very promptly after the use of the guaiacol.

By using the agent three or four times a day the temperature could be kept under control. He was not prepared, however, to say whether the drug used in this manner had any positive therapeutic value. At any rate it did not seem to act harmfully, and in some cases of tuberculosis it certainly had added to the comfort of the patients.

The method in which the drug applied externally caused lowering of the temperature, was not well understood. Given internally it had no such effect. He believed the same was true when it was inhaled. He had had no experience with it administered hypodermically. One French experimenter had made some investigations in order to determine the *modus operandi* of reduction of the temperature when the drug was applied to the skin, and had come to the conclusion that it was a reflex nervous effect, but Dr. Dana thought this view was hardly

tenable. The drug was undoubtedly absorbed, for it had been found in the urine of patients in whom it had been rubbed into the skin.

Dr. Dana said further, that he understood guaiacol was the active principle of creosote, creosote containing eighty or ninety per cent. of guaiacol, and producing an effect similar to that of the latter when rubbed into the skin. He had tried creosote once or twice, but found it a little more irritating than guaiacol, and therefore not so satisfactory. Dr. Farrington, at his suggestion, had tried eucalyptol in one case, but it had no effect. Since guaiacol seemed to act much like other antipyretics, it had occurred to him that it might have some anodyne effects, and in a case of sciatica in which it had been used Dr. Farrington reported that it had relieved pain quite promptly and seemed to have checked the course of the attack. Dr. Dana had also used it in some cases of neuralgia about the face and arms, but was not yet prepared to report the result.

Guaiacol—Its Mode of Reducing Temperature, was the title of a paper by Dr. W. Gilman Thompson, of New York. The fact that guaiacol is capable of reducing the body temperature in certain varieties of fever gives great interest to the probable physiological mode of action of this product. It is generally believed that the lowering of the body temperature is accomplished by the rapid absorption of the guaiacol which enters the circulation, and acts upon the heat-producing organs through the medium of the blood, after the manner of antipyrine, phenacetine, creosote, and other coal tar derivatives. This view is held by Bard,[1] Sciolla,[2] Robillard,[3] and others who have used the agent extensively. On the other hand, it is claimed by Guinard,[4] as a result of numerous experiments upon animals, that the heat-reduction occurs too promptly to be the result of absorption, and that it must therefore be due to cutaneous stimulation which affects the nerve-regulating mechanism of heat-production through the thermic centre. He states: First, that after ligation of the sciatic nerve in dogs guaiacol, applied to the skin of the leg, fails to reduce the temperature. Second, that when precautions are taken to exclude the vapor of guaiacol from the air inhaled, it never appears in the urine when rubbed into the skin. Third, that the drug acts more profoundly when the surface to which it is applied is kept covered, and that its effect is directly proportional to the extent of surface over which it is applied, and to the greater irritability of certain preparations.

I have recently experimented with guaiacol rubbed gently over the skin of various animals, and I find that in all cases it produces a very remarkable reduction of the normal rectal temperature. In dogs with a normal rectal temperature of 103.8° F., 10 gr. of guaiacol cause a reduction of 4.2°, which begins in about five minutes and continues for five or six hours, when the temperature rises slowly to normal, no other symptoms appearing. In the guinea-pig, with a normal temperature of 102.3° F., 5 gr. of guaiacol produce a reduction of 5° F. In rabbits with a normal temperature of 103 6° F., the reduction produced by five grains of guaiacol amounts to 7.6° F. in an hour. In the pigeon, whose normal rectal temperature is 109° F., I have observed a reduction of 10° in the course of seven hours. (In one of the cases of chronic bronchitis reported by Dr. Dana there was a fall of 9° F.)

To aid in determining whether the reduction was occasioned by increased heat loss, rather than by diminished heat production, I placed several animals in atmospheres slightly warmer than their normal body temperature, after a fall had commenced from the application of guaiacol, and in every instance the body temperature rose again to normal, but fell a second time on removing them to the temperature of the room. Thus to a pigeon with an initial temperature of 109° F., two grains of guaiacol were applied with a brush to the feet merely. In twenty minutes the temperature fell 1.5° F. On being placed in air of its own normal body temperature (which is cooler than that often temporarily inhaled by men and animals in the tropics, and, in fact, in certain parts of this country in midsummer), the rectal temperature rose in twenty minutes to 109.2° F., and again fell below 107° F. on removal. The animal meanwhile appeared in every way normal.

The remarkable changes of temperature which cold-blooded animals like the frog always undergo in adapting themselves to thermic alterations in their environment are not disturbed by guaiacol. A frog in water of 40°, 60°, or 80° F., still takes approximately the temperature of the fluid medium after one grain of guaiacol has been applied to it. Used in somewhat larger quantities, guaiacol is fatal to the lower animals in a few hours, death apparently resulting from heart failure, although the heart is usually found in systole. No macroscopic post-mortem changes are apparent.

For these reasons it does not seem possible that the drug acts in any other manner than by immediate absorption by the blood in the cutaneous vessels. It is difficult to conceive, as maintained by Guinard, that an agent which causes no apparent cutaneous irritation to either man or animals can cause death in the latter by purely reflex action through sensory nerve terminals. Moreover, agents like cantharides, iodine, and mustard, which produce far more local irritation, have no such extraordinary effect in reducing the body heat as measured by the thermometer. In regard to the sciatic nerve experiment above quoted, it should be borne in mind that this is a mixed nerve whose section and consequent irritation profoundly modify vascular tone, and may inhibit absorption as well as abolish the transmission of cutaneous nerve currents. If the drug does not reappear in the urine, as stated by Guinard, this does not necessarily disprove its absorption by the blood—too many different factors control its excretion. Moreover, others[1] have repeatedly observed its presence in the urine after inunction, and when precautions were taken to prevent the guaiacol vapor from entering the lungs.

If the effect of the drug applied to the leg is produced through the sciatic nerve terminals and not through the blood, then it should still act after everything in the leg but that nerve has been ligated. This experiment I performed upon an etherized animal in which the sciatic nerve was left uninjured while the remaining structures of the leg were all included in a very tight ligature. Guaiacol was then painted below the ligature, and during an hour's time there was no fall of temperature. As soon, however, as the opposite sound foot was painted with the guaiacol, the temperature fell at the rate of 1.5° F. in fifteen minutes. In another experiment the spinal cord was severed in an anæsthetized rabbit in the upper dorsal region, five grains of guaiacol were then rubbed into the groin, and in one hour the rectal temperature fell 7° F., but rose 3° when the animal was put for fifteen minutes into an atmosphere a few degrees warmer than its body. In this experiment there could have been no communication between the cutaneous nerves at the site of application of the drug and the medulla, and it must therefore have acted through absorption into the blood.

Whether this particular coal-tar product proves of clinical value or not upon further trial, it certainly possesses phenomenal power over the body temperature, and its method of application offers such decided advantages that one is led to hope that it may at least prove the forerunner of some new and valuable therapeutic agent of the same class.

Dr. Andrew H. Smith said that after having read Dr. DaCosta's article he had used guaiacol in a few cases at the Presbyterian Hospital, but the results had been so

uncertain that it had been abandoned. Sometimes the temperature fell a few degrees; sometimes it remained unchanged, so that the house-staff had come to take little interest in it.

Dr. Kinnicutt said, with regard to the internal administration of guaiacol, that he had found pretty large doses, twenty or thirty grains a day, produced no evil results. This remark applied to the carbonate also, and he suggested that since this form had not the disagreeable odor of guaiacol, it might perhaps be properly prepared and used externally instead of the latter.

Dr. Farrington was invited to make some remarks, and said that in most cases the fall in temperature was prompt, but in some it seemed to be delayed and did not take place until after the lapse of six or eight hours. The nurse rubbed the drug over six or eight inches square surface of the chest with the tips of her fingers. A strip of rubber prevented much odor spreading in the room. In phthisis, if the highest temperatnre took place at 5 P.M., he began using the guaiacol at 9 A.M., the temperature ceased to rise by 3 P.M., and was thus kept within reasonable bounds. The patients in whom it seemed to have no control over the fever yet expressed relief from the disagreeable paroxysm. Also where the temperature fell but a degree or half a degree, the patients had experienced great comfort from the drug. Only two patients among twenty five or thirty objected at all to the odor. Replying to a question, Dr. Farrington said the pure oil of guaiacol was rubbed on the skin, without admixture with other substances.

Modifications in the Technique of Vaginal Hysterectomy.—Dr. Clement Cleveland read the paper (see p. 777).

Dr. William M Polk thought it advantageous to elevate the buttocks while performing vaginal hysterectomy, since in that position the intestines gravitated out of the way. With a specially devised table the buttocks could readily be lowered during irrigation. The ligature carrier was a valuable instrument, one which he often used. He had not carried out Dr. Cleveland's method in its entirety, but did not doubt that it was a good one. Where the vagina was capacious and the uterus movable, vaginal hysterectomy could be performed with facility, but where the uterus was fixed it was a difficult operation. If in addition to immobility of the uterus the vagina were narrow, the difficulties became so great that he preferred to do the combined operation suggested by Dr. Cleveland some years ago.

Supposing the uterus were fairly movable, and it had been decided to do vaginal hysterectomy, the chief point was, how to control hemorrhage. The principal sources of hemorrhage were the uterine artery and vessels coming from the utero-sacral ligament. The latter constituted the source of annoying hemorrhage more frequently than some had appreciated. Dr. Polk's plan had been to cut down as nearly upon the artery as he could, beginning the incision at the side of the cervix, running down the vagina about an inch, introducing the finger through this opening, and separating the loose tissues about the lower portion of the uterus. If it seemed necessary he made another opening just back of the cervix, entering Douglas's pouch with one finger. Having thus gained access to and mapped out the uterine artery, he encircled it with a ligature carried up with a sort of aneurism needle, having a long shank. The farther out one ligated the vessel the less would be the hemorrhage, but care was required not to go so far as to injure the ureter. One could push the latter out of the way with the finger. It was now important to ligate the utero-sacral ligaments, after which there would be very little bleeding from the posterior wall. The bleeding from the anterior wall amounted to little and could be easily controlled. From this step Dr. Cleveland's suggestion regarding the method of amputation was very valuable. The field was cleared of tissue and any oozing points from vessels which might have escaped the primary ligatures, and, coming from the uterine vessels, could be easily secured. The only other source of hemorrhage would be the ovarian vessels, which one could include in a single ligature, after which the uterus could be removed.

Where the uterus was fixed he thought it better to work from above. The danger of infection, which was nearly always from the body of the uterus, could be obviated by packing with gauze. One could use the ligature below to secure the vaginal artery if he wished, and then open the abdomen and complete the operation from above. Here the advantages of the Trendelenburg posture were very great. Further, after opening the abdomen one could recognize enlarged glands which could not be felt from without, and perhaps learn that it would be useless to subject the woman to the dangers of total removal of the uterus.

Dr. W. T. Lusk said there was no doubt but what, by opening the posterior cul-de-sac and using the finger as a guide in tying the broad ligament, the operation was made very simple where there were no adhesions, but in such cases, the operation, he believed, was simple under any circumstances. But his own experience had been that, where there were adhesions, hysterectomy was not worth doing; the patients had died from three to six months after its performance, much sooner than where the operation had been limited to the lower uterine segment. Schroeder, who, during his lifetime, had been a strenuous supporter of hysterectomy, had admitted that after the malignant disease had advanced beyond a certain point, amputation of the lower uterine segment was followed by a more or less prolonged period of recovery, whereas total removal had led to a promptly fatal result. That had been Dr. Lusk's experience, but he would be glad to learn that that of others had been more favorable.

Dr. Robert Abbe had had no experience with removal of the cancerous uterus. He had operated a number of times for fibroids, not by the vaginal but by the abdominal method. He was under the impression that recent statistics favored the abdominal method in malignant disease also, on account of its enabling one to go out farther toward the side of the pelvis and thus get rid more completely of possible sources of infection. He thought the method described by Dr. Cleveland for removal of the uterus through the vagina must be a very good one. It seemed, however, that stripping the peritoneum up on the posterior wall of the uterus as far as possible above the cervix was unnecessary and objectionable, because, having been in so close contact with the malignant disease, it might be a source of reinfection.

Dr. Polk added that another advantage of the abdominal operation was the fact that it gave opportunity for extirpation of the upper vagina, which was important in cancer of the cervix. While the shock was greater in extirpation of the cancerous uterus from above than from below, yet supra-vaginal extirpation was in its infancy in this disease, and with further experience we had reason to believe the results would come to be much more favorable, as they were already in removal for fibroids.

Dr. Cleveland, in closing the discussion, said he thought Trendelenburg's position was an excellent one for doing the operation, but it was objectionable with regard to drainage. The blood settled toward the diaphragm, formed clots, and adhered to the intestine and all tissues with which it came in contact.

He did not believe in removal of the uterus for cancer when there were adhesions of much extent. If it were decided to remove the organ in the presence of extensive adhesions, it were better to operate through the abdomen, but for his own part he preferred to let such cases alone. As to removal of the tubes and ovaries, he thought that where the disease was not so extensive as to contra-indicate hysterectomy, it was just as well to leave those organs in; their presence made little difference if the patient had reached the menopause. In cancer of the body of the uterus, he thought Dr. Abbe's remarks held good.

Dr. Andrew H. Smith had used salicylic acid externally in the manner described by Dr. Kinnicutt, in one case of rheumatism affecting the ankle joint, the temper-

ature fell rapidly, and the effect had been very satisfactory.

Dr. Dana said that in his service at Bellevue he had had salicylic acid employed externally in a manner which he thought was even better than that described by Dr. Kinnicutt. The joint was painted with an alcoholic solution of salicylic acid and a little menthol. It was readily absorbed.

(To be concluded.)

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE INFLUENCE OF SOIL ON THE BACILLI OF CHOLERA AND TYPHOID.

London, May 30, 1894.

An important paper was read and discussed at the last meeting of the Medical and Chirurgical Society on the influence of different kinds of soil on the comma and typhoid organisms. It contains the result of a research which was carried out in Professor Macfadyen's laboratory at the British Institute of Preventive Medicine. This research was undertaken with a view to answering the following question: Had the soil in itself any action favorable or injurious to the life of the comma bacillus of cholera Asiatica and the bacillus of typhoid fever, or did the length of life of these organisms in soil simply depend upon the amount of moisture that might be present? The action of the saprophytic bacteria present in the soil was left out of consideration. Sterilized soils alone were used. The experiments were carried out with white crystal sand, yellow sand, garden earth, and peat. These were sterilized by means of moist heat. In white crystal sand, comma bacilli were alive on third but dead on fourth day; in yellow sand, alive on third but dead on fourth day; in garden earth, alive on third but dead on fourth day. The comma bacilli must have died, therefore, between the third and fourth days. Experiments were next made with a moist soil, which, however, contained no excess of moisture. In moist white crystal sand, comma bacilli were alive on the seventh day; in moist yellow sand, comma bacilli were alive on the thirty third day; in moist garden earth, they were alive on the thirty-third day.

Experiments were made to find the length of time comma bacilli would live in a soil when any excess of moisture was allowed to pass through the soil, but where little or no loss of moisture took place from the surface. Under such conditions the bacilli were alive in white crystal sand on the twenty-eighth day, in yellow sand on the sixty-eighth day, and in garden earth on the sixty-eighth day. In a soil deprived of its moisture the comma bacilli did not live longer than one to two days. In white silver sand, when moisture was allowed to escape, the bacilli were alive on the third day, but dead on the eighth day; but if evaporation of water was prevented, the comma bacilli were alive on the forty-seventh day. In white crystal sand, where evaporation was allowed to take place, the bacilli were still alive on the twenty-seventh day, with 1.57 per cent. of moisture in the sand. The bacilli were dead on the thirtieth day with 0.66 per cent. of moisture in the sand. When evaporation was prevented, the bacilli were alive on the one hundred and seventy-fourth day, and the sand still contained 7.1 per cent. of moisture: showing a close relation between the amount of moisture in the soil and the length of life of the organisms. With regard to peat, it was found that the comma bacilli were invariably dead in twenty four to twenty-six hours, independently of the amount of moisture that might be present. In sterilized 0.75 per cent. salt solution, the bacilli were still alive on the one hundred and seventy-fourth day. In sterilized urine the bacilli lived at blood-heat for fourteen days and at 22° C. for twenty-nine days.

Next as to the bacillus of typhoid fever on a dry soil where evaporation was allowed to take place: in white crystal sand the bacilli were found up to the ninth day, in yellow sand up to the eighteenth day, and in garden earth up to the fourteenth day; but in moist crystal sand the typhoid bacilli were alive on the twenty third day, in yellow sand and in garden earth on the forty-second day. On soils which had been deprived of their moisture the bacilli were only found up to the seventh day.

Experiments made with peat showed that on this soil the bacilli did not survive longer than twenty four hours. Peat was the only one of the four soils used which exercised a distinct destructive action on the organisms, independently of the amount of moisture present. Experiments made to test the filtering capacity of the soils showed that with a filter six inches thick, white crystal sand held back 99.6 per cent. comma bacilli, yellow sand held back 99 9 per cent. comma bacilli, garden earth held back eighty-nine per cent. comma bacilli, and peat held back one hundred per cent. comma bacilli. On the other hand, a current of water could carry the comma organisms through two feet and a half of porous soil. Conclusions: White crystal sand, yellow sand, and garden earth had no marked action on the organisms—their length of life in the soil depending chiefly on the amount of moisture. Peat, on the contrary, was very deadly to both the comma bacillus and the typhoid bacillus. The soil acted as a good filter, holding back most of the organisms; but it was possible for them to be carried through two feet and a half of porous soil by a current of water.

Brigade Surgeon Scriven said the research showed that one soil at least was hostile to the comma bacillus. In India they recognized certain places as being out of the cholera area, such as Multan in the Punjaub, while the neighboring district of Lahore was often decimated. It would be most useful to regiments moving to escape cholera to know of a soil deadly to the bacillus. Cholera did not last long upon a dry soil, but it was always present in damp Bengal, where cases often broke out apparently sporadically. The tendency of the research was to bring us nearer to acknowledging the possibility of the *de novo* production of disease; for if the bacillus could live for one hundred and seventy four days in soil, it would not be possible to prove its previous existence in another person.

Murchison held this view with regard to typhoid. While a moderate amount of wet was favorable to the development of cholera, a heavy rain was inimical, for it washed the bacilli down into the soil.

Dr. Washburn thought Dr. Dempster's research confirmed the work of previous workers, some of which he mentioned. He asked what was the reaction of peat and what salts it contained, and also if it contained a number of saprophytic bacteria.

Mr. Ward Humphreys said that the water-supply of Cheltenham had hitherto come from the hills, but it was now proposed to bring in a further supply from the Severn. The Worcester sewage went into the river just above the proposed intake, and asked if the well-known presence of peat in the Severn water would, in solution, act injuriously on any bacilli that might be present.

Dr. Kenneth MacLeod referred to the researches of Douglas Cunningham on typhoid bacilli in milk. He could not admit it to be absolutely demonstrated that the bacillus was the *causa causans* of cholera, though that view served as a good working hypothesis. Temperature was also important, and had a good deal to do with the development of cholera. There were degrees of moisture unfavorable to its development; too much moisture stopped it. Great excess and great diminution of heat were also unfavorable.

Dr. Cayley said that typhoid fever was at present extremely prevalent among the English troops in India, under circumstances which were not connected with the contamination of water or of milk, but it appeared to be spread by dust. As Uffelman had shown that the

bacillus of typhoid fever could live for ten weeks in dry earth and for forty days on dry wool, it was quite possible for bacilli in dust to be alive and active. If this were true it demonstrated the fallacy, in a dry country like India, of further developing the dry earth latrine system, for the earth impregnated with typhoid stools and spread upon the land might be one cause of the recent extension of typhoid fever in India.

Mr. Shirley Murphy said that the favorable action of moisture in the development of typhoid bacilli might help to account for its constant prevalence in certain districts in the East of London.

Dr. Allan Macfadyen replied, in the absence through illness of Dr. Dempster, who, he said, was aware, at the time that he started the investigations, that the path he was taking was not a novel one, but the importance of the subject led him to pursue it. He himself was of opinion that the truth lay between the view of Pettenhofer and that of Koch. Experiments conducted upon the surface soil were most important, because the surface-soil was most likely to be contaminated by pathogenic organisms from man, etc.; and acting as it did as an efficient filter, it retained a large number of such organisms in its upper layers. The deeper layers of the surface soil did not possess a suitable temperature for the continued life of pathogenic bacteria; and, again, the influence of saprophytic bacteria was only exerted in the uppermost layers of the soil. For practical purposes the surface-soil could be regarded as consisting of three layers: 1, The extreme superficial layer, which was usually either very dry or very moist; 2, an intermediate layer, which was always damp, and which did not admit of evaporation; and 3, a deeper layer, lying immediately above the subsoil, which was kept wet by capillarity from the subsoil. The three factors to be considered in studying the questions raised in the paper were the soil, the water, and the action of other bacteria. The paper itself dealt with the first two of these, and, with regard to the third, a later communication would be made; but they had ascertained already that organisms would live in soil a long time side by side with saprophytic organisms. Peat contained a large number of spores of bacteria, and a point for their future investigation would be to compare the number of bacteria present in peat with those in other soils. The peat was acid in reaction, and some complex soil acids were present. At present no direct experiments had been made with peat in solution. They were now engaged in working out the effect of the presence of filth on the growth of the micro-organisms. There was evidence to show that temperature also played an important part. The presence of summer heat and of a salt solution lengthened the life of a comma bacillus. In conclusion, Dr. Macfadyen bore testimony to the patience with which Dr. Dempster had conducted these experiments, and expressed gratitude to Mr. Cobb, the founder of the scholarship, who had so generously defrayed the expenses of this important research.

A REPLY FROM "FAIR PLAY."

To the Editor of the Medical Record.

Sir: Through some delay in my accustomed perusal of your interesting columns, I have only just learned, and to my surprise, that Dr. C. has undertaken to reply to my discussion of an important general principle:

1, By recapitulating the facts I had already related;

2, By dragging into the controversy a number of personal details, entirely irrelevant to the question at issue. I had no personal grievance against Dr. C. (unless that he took no notice of my personal written protest until it had appeared in carefully veiled form in the Medical Record); and had I had one, I should not have burdened even your friendly columns with it. But I am seriously interested in principles of delicate honor and sincerity in professional relations; and have always felt that both were liable to be lacking when the famous New Code principles, about which so much controversy was waged, should be applied in practice. So I find reiterated observations of facts, near at hand to me, have taught me that it is very possible to build up a large family practice, though invariably refusing to accept a call from any one but the patient or the really responsible member of the family; and a large consulting practice, though steadily declining to listen to the "dictates of humanity" in regard to Mr. A., B., or C. who "was very ill," unless at the written or oral request of the attending physician. It is therefore not only theoretically just, but practically useful, both to self and patient, to be, first, a physician; secondly, a man; and thirdly, a man of business; and it is not necessary in any interest to reverse this order of sequence.

Pardon me for this further intrusion on your valuable space, which trespass I will not again commit.

Fair Play.

Therapeutic Hints.

Perityphlitis.—One hundred cases of peritionitis from perforation of the vermiform appendix were found in 18,000 autopsies in the Pathological Institute of Munich. Ninety-one per cent. of the cases are due to perforation of the appendix. Primary perforation of the cæcum occurs in only nine per cent. Perforation of the vermiform process is seldom caused by the presence of foreign bodies, and in such cases usually by hardened and inspissated masses of fæcal matter.—H. Einhorn.

Tetanoid Convulsions of Peripheral Origin in an Infant.—Excision of umbilicus, immediate improvement.—Ronaldson.

Intussusception.—Inflation does not appear to be safer than injection, and neither is advisable as a prelude to laparotomy.—Mortimer.

Appendicitis.—By the second or third day, and with strong reasons later, the operation should be done if the following indications are present: 1. If there is abdominal pain most marked in the right iliac fossa. 2. If there is rigidity of the right abdominal wall. 3. If there is fever up to 100 or 102 degrees F. 4. If by a minute and careful palpation tumefaction and increased resistance can be discovered, with possible dulness and rarely fluctuation. 5. If there is œdema of the abdominal wall.—Keen.

Bromides, combined with opium, will often prevent the nauseating effects that opium has on many persons.—Hare.

Chloral, when the nervous irritability of alcoholism requires it as a sedative, should be combined with strychnine.—Hare.

Picric Acid for Superficial Burns.—Wet gauze compresses with a saturated solution of picric acid, wring them dry, and apply directly to the surface of superficial burns. If the dressing remains antiseptic, it does not require frequent changing, not oftener than every three days at first, then every five days. No impermeable protective covering is necessary, for the gauze compresses dry on the burn. Picric acid is antiseptic and healing, and allays pain.—Tilleul.

Protection of Boys from Assault.—Mr. Tait insists that the criminal law should be amended in order to protect boys against being induced by adult women to have sexual intercourse with them. According to Mr. Tait this is by no means a rare offence; "relatively," he says, "I am not sure if it is not as common as its converse." There is no doubt that, while every protection is afforded to the female sex by the act in question, the male sex are placed at a great disadvantage, not only in the manner pointed out by Mr. Tait, but also in the power which women possess of bringing false charges against men.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 16, 1894.

	Cases.	Deaths.
Tuberculosis	145	94
Typhoid fever	10	4
Scarlet fever	114	18
Cerebro-spinal meningitis	5	6
Measles	122	9
Diphtheria	244	43
Small-pox	15	3
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

Guaiacol is recommended for the relief of various neuralgic and muscular pains. It is mixed with equal parts of glycerine and applied to the painful region.

Disease in Railroad Coaches —In the laboratory of the Imperial Board of Health of Germany experiments have recently been made which show that the seeds of consumption were found in abundance in the dust collected, not only on the floors, but on the walls and seats of carriages. Samples of dust were taken from 45 compartments of 21 different passenger cars and 117 animals were inoculated with them. Part of these died very soon thereafter of various contagious diseases before they had time to develop consumption; of the rest, killed four to six weeks after inoculation, three had tubercles. These three, however, were inoculated with sleeping-carriage dust, taken, not from the floor, but from the walls, cushions, and ceilings. Bacteria at the rate of 78,800 per square inch were found on the floor of a fourth class carriage, and 34,400, 27,000, and 16,500 per square inch on the floors of the third, second, and first-class carriages. Thus, even in the latter, the average passenger, who usually has at least half a compartment to himself, say 3.000 square inches of floor, has an army of 49,500,000 deadly enemies aiming at his vitals on the floor alone, to say nothing of other millions in front and rear, on both flanks, and overhead. It would seem impossible to escape; but the Board of Health is said to have reported measures for removing or reducing the danger which the railroads are considering.

Glycerophosphates and their Therapeutical Uses.—Dr. Albert Robin, professeur-agrégé of the Paris Faculty, can lay claim to the distinction of having created as much sensation last week by the announcement of his discovery of the glycerophosphatic treatment as the late Dr. Brown-Séquard did with his orchitic extract. Inspired by the fact that many neurasthenics void in their urine comparatively large quantities of incompletely oxidized phosphorus, the source of which is probably the lecithin of the nerve-tissues, the idea occurred to him that this nerve waste could be best met by supplying the system with phosphorus in organic combination most nearly approaching to that under which it exists as lecithin in the nerve centres. Since 1888 Dr. Robin has experimented with the glycerophosphates of calcium, sodium, and potassium, either isolated or associated, and both subcutaneously and through the stomach. He asserts that their influence on nutrition is indisputable. Thus, the hypodermic injection of twenty-five centigrammes of glycerophosphate of lime increases the total residue of the urine, the only ingredients remaining unaffected being the uric and phosphoric acids, the latter body appearing to undergo diminution. The glycerophosphates seem to act antagonistically to antipyrin, which is the remedy for heightened nervous excitability. Their action when swallowed is less marked than when they are introduced into the system through the lymphatics. Dr. Robin claims to have had successes in the following conditions: convalescence from influenza, and certain infectious diseases; nervous depression; neurasthenic phosphaturia; torpid form of chlorosis characterized by diminished oxidation of proteids; phosphaturic albuminuria; and simple phosphaturia. He further cites the case of a young man, aged twenty three, affected with Addison's disease, and very thin and weak. Twenty five centigrammes of glycerophosphate of lime injected subcutaneously daily, from January 5th to the 25th, brought up his weight from fifty six to fifty-nine kilogrammes, and restored his strength in a remarkable degree. He resumed his work on February 9th, and the improvement had continued up to April 5th, although the pigmentation persisted. Dr. Robin opines that the really active agent in testicular juice is phosphorus in organic combination, and that its frequent failure in this form may be explained by the instability of the gland extract. This instability is avoided when the artificial product is employed.—*The Lancet.*

From Iron to Hæmoglobin.—The absorption of iron by the body, though very important and interesting, is exceedingly difficult to trace, because when iron unites with organic substances its reactions are masked. The investigations of Professor A. B. Macallum, of Toronto University, lead him to conclude that hæmoglobin is formed from nuclein, and possibly from prozymogen. His experiments in feeding the inorganic compounds of iron to guinea-pigs and other animals showed that the intestinal mucosa absorbed these to an extent which varied with the nature of the compound and with the quantity fed. With small doses absorption occurred only in that portion of the small intestine adjacent to the pylorus, extending only a few inches from the stomach. When one large dose was given, the absorptive area sometimes included all of the small intestine. With the small dose the result appears to depend on the complete precipitation, as hydroxide, of the iron of the salt unabsorbed in the thoroughly mixed bile, chyme, and pancreatic juice. With one large dose the alkalinity of those fluids is first destroyed by the iron salt, the great excess of which is unaffected, and remaining in solution undergoes absorption. When the amount absorbed is small, the intestinal epithelial cells transfer the absorbed iron at once to the underlying elements, but with a large amount absorbed the epithelial cells are found to contain some of it. A part of the absorbed iron is carried into the general blood circulation by the sub-epithelial leucocytes of the villi, but it is probable that the blood plasma is the more important agent in the transferrence of the inorganic iron to other parts of the body. The administration of the albuminate or of the peptonate of iron to guinea-pigs seemed to stimulate the leucocytes to invade the epithelial layer of the intestinal villi. The mode of absorption of the organic compound of iron present in egg-yolk was obscure, but the process seemed to be connected with the fat which is so closely associated with the iron compound formed in egg-yolk. The liver and the kidney, in man, are the most active organs in the excretion of any excess of iron thus absorbed by the lining cells of the small intestine to help form the hæmoglobin of the red blood-cell.

The Holy Coat of Treves.—The Bishop of Treves has published a book recounting eleven miraculous cures effected during the exposition of the Holy Coat in that city in 1891. One case was that of a child named Wecker, who, according to a certificate signed by Dr. Koeller, of Berlin, was suffering from intestinal tuberculosis. He was taken to Treves and allowed to touch the relic, and was then pronounced cured. Drs. Koeller and Schultze, of Berlin, certify that the boy is now in good health. The good bishop holds that the boy could not have been cured by natural means, and that therefore his present condition of health is evidence that a miracle has taken place.

A CASE OF ACUTE INFLAMMATION OF THE MIDDLE EAR, TERMINATING IN PURULENT PERIPHLEBITIS OF THE LATERAL SINUS; OPERATION; RECOVERY.[1]

BY ALBERT H. BUCK, M.D.,

NEW YORK.

CLINICAL PROFESSOR OF THE DISEASES OF THE EAR, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA COLLEGE, NEW YORK; CONSULTING AURAL SURGEON, NEW YORK EYE AND EAR INFIRMARY AND THE PRESBYTERIAN HOSPITAL.

THE patient, a man of strong physique, about fifty four years of age, consulted me on January 29, 1894, for the relief of pain in the left ear. For several days previously he had been suffering from a "cold in the head," and on the preceding day he had taken a sleigh ride; but he had not been conscious of having experienced at the time any chilling of the body. The pain had first been felt early in the morning of the day following that on which he took the sleigh ride—that is, only a few hours before he came to my office. I examined the ear, and found the membrana tympani, especially the upper half, markedly hyperæmic. There was also a decidedly congested and swollen condition of the naso pharyngeal mucous membrane. No secretion had as yet accumulated in the drum cavity. An application of a fifteen-grain silver nitrate solution was made to the vault of the pharynx, and hot poulticing and rest in bed were prescribed.

On the following day I visited the patient at his home, and found that he had experienced very little if any relief from the pain in the ear. The appearance of the drum membrane showed that the drum cavity was already full of secretion and that the inflammation was increasing in violence, despite the hot and moist applications. I accordingly made a long, crescent shaped incision in the posterior half of the membrane, affording a free outlet to the pent-up, blood-stained serum, and I ordered a continuance of the poulticing and the free use of the hot-water douche.

The paracentesis afforded a measurable degree of relief, but only for a short time. On February 3d, 5th, 7th, and 10th it was found necessary, on account of the rapidity with which the opening healed, and on account of the return of pain whenever the opening ceased to be of fairly large size, to repeat the paracentesis. Soon after the first operation the discharge became purulent in character and quite abundant. On February 11th or 12th there was slight tenderness on pressure behind the ear, and accordingly three leeches were applied to this region.

On the 14th, as the leeches had afforded only temporary relief, a Wilde's incision was made; and on the following day a seton was established at this point. A very broad, curved needle (made specially for the purpose), with cutting edges and armed with six or eight threads of coarse silk, was introduced at the bottom of the Wilde's incision and pushed out backward through the skin at a spot about one inch distant from the point where it had entered.

The discharge from this artificial sinus, kept in an irritated condition by the presence of the mass of silk, failed to exert any marked impression upon the amount of discharge from the middle ear or upon the subjective pain experienced by the patient. After the seton had been in place for four or five days, the patient had a sharp chill, which lasted for a few minutes, but was not followed by any appreciable rise in temperature. (The patient's body temperature was tested nearly every day and sometimes twice a day, but it was always found to be either normal, or at most two- or three-tenths of a degree above the normal.) At the time, I felt confident that this chill was due to the imprisonment of pus in the seton channel; for when I examined the parts, one or two hours afterward, I found both orifices practically closed by the drying up and caking of the discharge at these points, and even in the light of later developments I am still disposed to look upon this as the correct explanation.

On February 21st Dr. Herman Knapp saw the patient with me in consultation. The pain had not been materially diminished by any of the measures which I had instituted—repeated paracenteses, hot poulticing and frequent douching of the external auditory canal, the application of leeches to the mastoid region, a Wilde's incision followed by the introduction of a seton, an occasional dose of calomel, the daily employment of the Carlsbad Sprudel salts, etc.—and it was becoming more distinctly hemicranial in character. I therefore felt that the time had arrived when it would be wise to establish a free outlet from the mastoid antrum through the mass of bone lying outside of it. On this particular day, however, the patient felt decidedly better than he had felt for several days previously, and we accordingly agreed to postpone, at least for the moment, the consideration of the question of operative interference. It was decided, however, to remove the seton, for it was apparently accomplishing no good purpose, and yet, at the same time, it was preventing us from estimating correctly, by aid of such signs as tenderness on pressure, swelling, etc., of the skin, how the underlying mastoid inflammation was behaving. Dr. Knapp's examination of the patient's left eye with the ophthalmoscope gave a negative result.

On the following day (February 22d), the patient once more complained of decided pain in and around the ear; and, as the opening in the drum membrane had by this time again become insufficiently large for free drainage of the inflamed middle ear, I excised a small portion of it by first making a flap (with its base below) and then snaring off its upper free extremity. The incision which marked the posterior limit of this flap approached very closely to the curved line corresponding to the insertion of the membrana tympani in the sulcus tympanicus, and as the knife passed through the thickened tissues of the membrane there was a sudden escape of thick creamy pus quite different from the muco purulent secretion escaping from the old opening in the membrane. By further manipulations I succeeded in dislodging, through the opening, a core-like mass as large as a No. 3 shot. The introduction of a bent middle-ear probe revealed the fact that the posterior wall of the cavity from which this creamy pus and this core-like mass of broken down tissue had been evacuated was bone denuded of its covering of mucous membrane. In other words, I had accidentally evacuated a separate collection of pus, located at the posterior end of the tympanic cavity, between the surface of the bone and the mucous membrane (periosteum) just beneath the entrance to the mastoid antrum. In the natural state the bone at this point is somewhat rough and irregular. From the sense

[1] Paper read before the American Otological Society at its meeting in Washington, D. C., May 29, 1894.

of touch alone, therefore, I could draw no safe conclusion as to its condition. There could be no doubt, however, about its being in a state of inflammation.

The relief afforded by this operation was but very little if at all greater than that afforded by my previous simple paracenteses.

On March 1st Dr. Knapp again saw the patient with me, and it was decided to cut down to the antrum. The operation was performed in the usual manner. No well-marked pneumatic cells were encountered until I had chiselled away the bone to a depth of nearly half an inch. These cells were all found to be filled with granulation tissue, and at all points the bone substance was found to be in a condition of marked hyperæmia. Close to the antrum, however, it was found to be of a bluish-black color and softened. No pus was encountered until the antrum was reached, and then only a barely recognizable amount. Every portion of the wound, the antrum, and the tympanic cavity proper, was thoroughly irrigated with a 1 to 4,000 bichloride solution: the fluid escaping freely from the middle ear into the external auditory canal. No sutures were employed, and the wound was dressed with iodoform gauze.

From March 1st to the 16th nothing worthy of special note occurred. The operation caused the pain to almost disappear at first, but gradually it returned and steadily increased up to the date last mentioned. Then, in the belief that there might perhaps be some obstruction to the free escape of pus, I reopened the wound freely, and, with a Volkmann's spoon, cleared away all the granulation tissue which had formed in the antrum and in the excavation made in the bone, outside of the antrum. This procedure, however, afforded only temporary relief. From time to time during the following three weeks I tried different kinds of drainage-tubes and contrivances, in the hope of securing complete freedom from pressure upon the mass of escaping pus; for whenever I succeeded in accomplishing this, even for a short time, I observed that the patient experienced comparative freedom from pain. But the discharge was abundant and granulation tissue repeatedly blocked the openings in the drainage-tube, thus re establishing the condition of pressure which was so undesirable. It was during this period that the patient had the second and last chill that he experienced during the entire illness. The drainage-tube, at the time, was completely blocked, and there was an appreciable increase in tension of the skin surrounding the outlet. I am unable to state whether this second chill was or was not associated with a rise in the body temperature.

Toward the end of the period now under consideration there was a noticeable increase in the redness and swelling of the integuments covering the lower and posterior part of the mastoid process, and the lateral movements of the head caused some distress. But there was no tenderness along the side of the neck, and the tenderness over the tip and posterior aspect of the mastoid bone was but little if at all greater than one usually finds in the vicinity of a still open mastoid wound. The discharge, however, was more copious than it should be from such a wound, and I made up my mind that there must be a centre of active osteitis in the lower part of the mastoid bone. Accordingly, on April 9th, the patient was put under the influence of chloroform, and a considerable portion of the lower part of the mastoid process was removed by chiselling. No centre of pus was found, but everywhere the bone appeared to be in a markedly hyperæmic state.

During the week following this operation the patient's condition steadily grew worse in the following respects: The movements of the head became more painful, there began to be an appreciable degree of tenderness below the mastoid process, and the swelling, tenderness, and pain in the region lying between the mastoid bone and the occiput increased to an appreciable degree. Then, besides, he found that he could read for only a short time, on account of the pain which it produced in the left eye. On the other hand, the body temperature did not rise above 99 4° F., the pulse-rate did not exceed eighty two beats to the minute, and the patient continued to take his food with relish. The symptoms just enumerated, however, satisfied me that the inflammation was extending in a backward and perhaps inward direction, and that a bolder search for some centre of pus should be made in these directions. This conclusion was still further strengthened by my finding, on April 13th, that pus from some new source, situated below the artificial opening in the bone, was burrowing down the side of the neck in front of the sterno cleido mastoid muscle.

On April 14th the patient was brought under the influence of chloroform, and I proceeded to chisel away the outer and posterior surface of the mastoid process. At all points the bone was found to be markedly hyperæmic, but no pus or appreciable softening of the bone substance was found until the immediate wall of the channel for the lateral sinus (sigmoid groove) was reached. At this point, situated at a depth of fully half an inch from the outer surface of the mastoid process, the bone seemed to have undergone a certain degree of softening, and odorless, creamy pus welled up from this cavity as soon as the chisel cut through the surrounding softened wall of bone. By means partly of the chisel and partly of a medium-sized Volkmann's spoon I enlarged the opening until it measured about three-eighths of an inch in diameter. The outer wall of the exposed vein was found to be granulating, but not softened, so far as I could judge from pressure with the probe. The absence of all tension warranted the belief that the vein was thrombosed at this point. So far as I could judge, the pus surrounding the vein came partly from some point higher up and partly from below. I fully expected to discover roughened bone, or the opening of a fistula, at some point along the anterior aspect of the sigmoid groove; but my probe revealed no such point.

The situation of affairs, as brought to light more fully by this operation, made me feel that I could no longer do full justice to the case; that, in the further search for centres of pus, regions would have to be laid bare with which I did not feel myself to be sufficiently familiar; and that, therefore, a general surgeon should be summoned. Accordingly, Dr. Theodore Lange was invited to take charge. The patient was once more anæsthetized (April 16th), and Dr. Lange proceeded first to expose thoroughly the downward track of the pus along the jugular vein. Then he removed, by chiselling and by the use of the rongeur forceps, all that remained of the mastoid process; thus laying bare the jugular vein from its situation in the sigmoid groove down to a point perhaps one inch below the level of the tip of the mastoid process. All of the jugular vein thus exposed to view was evidently in a thrombosed condition, as its walls showed no changes in tension when firm pressure was made upon the side of the neck, lower down, or when the patient coughed. Dr. Lange also removed, in an upward direction, enough of the squamous portion of the temporal bone, where it forms the outer wall of the vertical part of the lateral sinus, to give him free access to any collection of pus that might exist in this part of the cranial cavity. No such collection, however, was found. Then, finally, he worked his way cautiously downward and inward until he had exposed the styloid process, the trunk of the facial nerve as it emerges from the stylo mastoid foramen, and the region beneath the foramen lacerum. The probe was passed through this opening into the cranial cavity; but no collection of pus was found. All this work, I scarcely need to state, was performed under constant aseptic and antiseptic precautions. After the operation was completed, a drainage-tube was laid in the wound, with its inner end resting against the deepest part of the excavation, and iodoform gauze was packed around it. A few turns of a bichloride gauze bandage served to keep the dressings well in place.

On the day following the operation the temperature

rose to 100.4° F., and then gradually fell, during the course of the following week, to normal. The pain in the left eye brought on by reading, gradually disappeared, and with it the slight alterations observed by Dr. Knapp, shortly after the operation, in the fundus of the eye. At the end of three weeks the patient was allowed to leave his bed, and at the present time of writing (May 27th), the wound has progressed so far toward healing that its complete cicatrization may be looked for in the course of the next two or three weeks. No drawbacks of any kind have occurred during this period.

The discharge from the middle ear, by way of the external auditory canal, ceased on the third or fourth day after the first operation upon the mastoid process; but on two or three subsequent occasions it returned for brief periods of time. It was not clear to what these slight relapses were due; but it is probable that some interference with the drainage from the antrum, by way of the outside wound, caused sufficient back pressure to reopen the perforation in the membrana tympani.

Throughout almost the entire attack the hearing in the affected ear remained fairly good, and soon after the last operation it returned to a practically normal condition.

Comments.—The most striking feature in this case, as it seems to me, is to be found in the fact that the disease began, almost at the very start, as an osteitis. There was, it is true, the usual antecedent naso-pharyngeal inflammation, and this inflammation spread in the usual manner to the mucous membrane of the middle ear. But the course which it pursued, after it had reached the latter cavity, was certainly very different from that which we are accustomed to see in the vast majority of cases. I have often said to myself, and have perhaps expressed the view to others, that if an acute inflammation of the middle ear (not associated with diphtheria, measles, scarlet fever, small pox, or typhoid fever) could be subjected to suitable treatment within the first twenty-four hours it would never progress so far as to seriously involve the neighboring mastoid process. In the present instance the patient presented himself within a few hours of the time when he felt the first twinges of pain in the ear. Simple antiphlogistic measures were employed immediately, and then, as soon as any secretion had accumulated in the drum cavity—that is, at the end of twenty-four hours—a very free opening was made in the drum membrane, in order that intra-tympanic pressure—the factor which is believed to play perhaps the most important part in the aggravation and further spread of an acute middle-ear inflammation—might be quickly done away with. But it is evident that in the present instance only a very transient beneficial effect was produced by this and the succeeding efforts to reduce intra-tympanic pressure to a minimum, or by the other antiphlogistic measures employed. The most plausible explanation of this lack of success in arresting the inflammation is to be found, I believe, in the assumption—which is strengthened by the facts revealed in the later course of the disease—that already at this early stage the inflammation of the adjacent bone, particularly that portion which lies near the posterior end of the tympanum and around the antrum, had gathered considerable headway. It is not unlikely, furthermore, that there may have been certain anatomical peculiarities which rendered this mastoid bone more than ordinarily liable to participate in any inflammation that might develop in the contiguous tympanic mucous membrane. As favoring this view, I may mention the facts that seventeen years ago I operated upon this same patient's right mastoid process, and that one of the most troublesome features in the case was an obstinate tendency to the formation of firm granulation-tissue around a small spot of bone caries situated at the posterior end of the tympanum, just beneath the entrance to the antrum.

The absence of fever and of chills (the two mentioned in the history of the case were, I believe, due to special conditions) may also be noted as something unusual. The absence of these symptoms probably indicated that up to the time of my last operation the inflammation had not gone much beyond the stage of periphlebitis of the lateral sinus, and that whatever actual phlebitis existed must have been of a mild, non-infective character, simply active enough to create a thrombus.

The present case and others of a more or less similar nature that are to be found recorded in medical literature justify the establishment of a rule something like the following: *The persistence of deep seated pain behind the mastoid process, continuing after the antrum has been opened into and thoroughly drained, is sufficient warrant for making an opening into the sigmoid groove for the lateral sinus; and it is not advisable to wait until the patient has chills, or until the body temperature rises to an appreciable degree, before resorting to operative interference in this direction.* If we wait for the corroborative evidence furnished by the symptoms last named, we shall lose lives that might otherwise be saved.

SCORBUTUS IN INFANCY.

By WALTER LESTER CARR, M.D.,

NEW YORK.

As an introduction to a brief clinical paper on "Scorbutus in Infancy," the following report of a case is of interest.[2]

A. W——, male, born January 26, 1893, was nursed for a few days and then given cow's milk, as his mother's supply failed, owing to her want of strength caused by nephritis. The baby thrived on cow's milk and was a well-nourished, healthy infant. At the age of five months he was taken away from New York, and the food was changed to malted milk, which was afterward replaced by lacta preparata. From the mother I learned the following:

In July the baby had diarrhœa, which increased in severity and was accompanied by vomiting. There was, probably, an entero colitis, as blood and mucus were seen in the movements, which were very offensive. "Small spots like bites" were observed on the body and legs, but ecchymoses were not noticed. The proprietary food was persisted in, although the baby failed to improve with its use. Swellings appeared around the knee joints and were spoken of as "rheumatic." A grave prognosis was given.

The infant was aged nine months when he was brought back to New York. When I first saw him he was lying extended on a pillow, and did not seem to have enough strength to move. He was extremely emaciated and anæmic. His face wore an anxious expression and his complexion was an earthy white. The skin was dry and desquamating. There was a papular eruption on the upper part of the trunk and the buttocks were erythematous. There were no evidences of subcutaneous hemorrhages or discolorations. The head was comparatively large, with the forehead square and the anterior fontanelle well open. The back of the head was almost denuded of hair, and was bathed in a profuse perspiration which wet the pillow. The neck and shoulders showed the same transudation. There was no cranio tabes. The examination of the occipital region occasioned pain, but not more severe than when any part of the body was handled. The dread of being touched was so great that the little patient would utter agonizing screams whenever anyone came near him. When he cried he did not move his limbs as is observed in a healthy baby. The thighs were swollen over the lower half, but the swellings did not extend into the joints, being limited by the epiphyseal junction. The right thigh was larger than the left. Enlargement of the epiphyses was evident. Below the knees there were swellings over the tibiæ. The synovial sheaths did not appear to have undergone any change; it was impossible to detect thickening or increase of fluid. Induration or œdema of the muscles did not exist.

[1] Read before the Medical Society of the County of New York, April 23, 1894, and by invitation before the Medical Society of New Jersey, June 27, 1894.

[2] See also report of Case of Scorbutus in an Infant, MEDICAL RECORD, October, 8, 1892.

The skin was not glazed, nor was there heat, redness, or venous stasis. Bony crepitus could not be elicited.

The forearms presented well-marked swellings over the lower ends of radii and ulnæ, just above their epiphyseal lines—the left arm being more enlarged than the right. The swellings covered the lower third of the shafts of the bones. A considerable enlargement of the distal epiphyses gave further evidence, if that were needed, of the rachitis. The upper third of the humeri were exquisitely tender, but no swellings could be detected. The scapulæ were not thickened. The ankles were slightly œdematous but the hip- and elbow-joints were normal. The ribs were not beaded, but the thorax was indented corresponding to the attachments of the diaphragm. A few, large moist râles were heard over the lungs. The abdomen was not enlarged, but was tender on pressure. The liver and spleen were normal. The lymphatic glands in the groins and cervical region were as large as peas and could be rolled under the fingers. The gums were not swollen, and petechiæ were not to be seen. As the teeth had not been erupted the appearance of the mouth could not be accepted as diagnostic. The tongue had a yellowish-white coating, and the breath was not offensive. All of the mucous membrane was pale. The temperature in the rectum was 100° F.; the pulse was 122, and the respirations 27. The urine was normal. The blood was not examined.

A trained nurse was secured for the baby, and he was placed in her care with orders to feed him fresh beef juice, fresh milk, orange juice, and brandy. The brandy was ordered because of the extreme weakness. Paregoric was administered to ease the pain and relieve the intestinal irritation. Local applications of alcohol and belladonna liniment, diluted, were made to the swollen parts.

From the first feeding with fresh food improvement was noted. The baby began to use his limbs soon after he was fed the anti scorbutic diet. Although he was still emaciated the tenderness lessened, and he was able to bear handling. The arms improved first, and he used them at the end of a week. The subsidence of the swellings of the thighs left a thickening of the periosteum which could be felt for two or three weeks longer.

The movements from the bowels, which had been frequent, very fetid, and contained mucus, improved with the changed diet. Irrigation had, apparently, a favorable influence.

The temperature range for the first week of treatment was 99° to 102° F. The highest temperature was observed in the morning; the afternoon point was always lower.

The baby made steady progress, and although all signs of rachitis have not disappeared, the scorbutus, except for the anæmia, has left no trace.

We have here the history of a baby who, though bottle-fed, was healthy until he was over five months of age. With a change in location and diet he had dyspepsia, enterocolitis, and atrophy. Accompanying these disorders of digestion and nutrition, there were disinclination to use the extremities, swellings on the shafts of the long bones, most noticeable on the femora, and great tenderness over all the body.

A diagnosis of scurvy could be made from the history. To be sure, the gums were not bleeding, but swelling and hemorrhage are not often present when the teeth have not appeared, and are not always seen even in severe cases after dentition.

The dietetic management of the case gave such immediate relief that, had any further confirmation been required, we would have had it in the prompt recovery of the baby from all scorbutic symptoms.

Scorbutus in childhood and infancy is a rare disease. Its occurrence is due to faulty methods of feeding, which are easy of correction. If the symptoms are appreciated a change in diet, without medicinal measures, will effect a cure; but if the scorbutus is not relieved it often progresses to a fatal ending.

The rarity of scurvy among dispensary patients is to be seen by the figures taken from my records of the Children's Class, in the Out-door Department of Bellevue Hospital, by Dr. G. E. Neuhaus. Of 2,352 patients treated in eighteen months, there were 264 with rickets, or 11.23 per cent., and among the whole number there was only one case of scorbutus. My service of one thousand new patients at the Out-patient Department, St. Mary's Free Hospital for Children, did not furnish one child with scurvy. Dr. H. R Purdy had but one case during a year's service at the Dispensary of the Church Hospital. The comparative infrequency of the disease is commented upon by Northrup, who has furnished us with a history of scurvy as it has been observed in this country.

As practitioners come to have a more accurate knowledge of scorbutus, the number of cases recorded will, without doubt, be much greater.

The disease is commonest under the age of two years, and in artificially fed babies. After two years a child has a varied diet, and unless there is an actual deprivation of fresh food, he is not so liable to become scorbutic.

Scurvy is a blood dyscrasia due to nutritive disturbances occasioned by the want of fresh food, especially by the absence of vegetable and fruit acids. Bacteria undoubtedly have a part in its production. Some observers believe that purpura and scurvy are identical, and are caused by the same micro-organism, but this is not yet accepted.

As it is observed during the two first years of life, scorbutus presents symptoms which conform to the disease as it is seen later, but during infancy other evidences of malnutrition may divert attention from the scurvy. Rickets is a state of the system due to imperfect nutrition, with which scorbutus may coexist.

Cheadle [1] questions whether the cases of acute rickets are not in reality rickets with a mild degree of scurvy. The dietetic errors which cause rickets will, in a certain percentage of cases, add scurvy to it. In private practice among the well-to-do and wealthy, an artificially fed baby is provided with one food, often proprietary, which is given at regular intervals. If the food does not contain the ingredients required, scurvy may be added to rachitis, because no opportunity is afforded the baby to get anti-scorbutic food. Among the poorer classes the baby has more latitude, and although the diet may not furnish material that will prevent rickets, yet he is fed from the table and so secures articles, especially potatoes, which are anti-scorbutic.

The symptoms that are regarded as diagnostic and that are usually present are:

1. Swellings of the limbs, most commonly the thigh, with extreme tenderness and pseudo paralysis.
2. Changes in the gums, which may be swollen and bleeding, or show only a few hemorrhagic spots.
3. Vascular changes in the skin and mucous membranes: petechiæ, ecchymoses, and hemorrhages.
4. Irritability and other disturbances of the nervous system.
5. Anæmia, wasting, and loss of strength.

The three first symptoms are the most palpable, but the irritability and anæmia precede the more conspicuous signs, which we shall study first.

It is a matter of anatomical interest that the greatest hemorrhage and swelling occur at the lower end of the femur. The epiphysis of this bone is the first to appear and the last to ossify. The nutrient arteries of the lower extremity are directed away from the knee-joint. In infants the subperiosteal hemorrhages are more common than in adults, because of the growth of bone tissue.

The hemorrhage between the periosteum and bone produces the swelling and occasions the pain by stretching the membrane. The effects of this subperiosteal hemorrhage are, as has been mentioned, most frequently observed in the femur.

The swelling of the thigh is sausage-shaped or fusiform,

[1] Artificial Feeding and Food Disorders of Children.

and extends one-third or more of the length of the bone. The greatest enlargement is at the lower end. If both thighs are involved one is usually larger than the other. The skin of the affected part is white, smooth, and does not pit on pressure, unless there is infiltration of the muscles. The superficial veins may be distinct but heat and redness are rare. If œdema be present it is usually of the thigh or foot.

When the tibia is implicated and the swelling is both below and above the knee joint, there may be superficial evidence of synovial effusion, which an examination will show is caused by the changes in the bones, and not from fluid in the joint. The fibula is not diseased with the same frequency as the tibia.

The limb is kept as quiet as possible, as the baby dreads the slightest movement. Early in the disease the position is one of semi-flexion, but later the limb is extended and there is pseudo paralysis. When the epiphysis is separated the part can be handled with less pain than in the early stages.

The bones of the forearm at the wrist are, next to the femur and tibia, the most frequent sites of periosteal extravasation. The swelling is not so extensive as is observed in the lower extremity. The shafts of the bones show plainly the limitation of the hemorrhagic tumor at the epiphyseal line.

The arm is not affected so often as the forearm, and when it is the upper end of the humerus is involved. The bones at the elbow do not seem to suffer. Other bones liable to subperiosteal hemorrhage are the scapulæ, ribs, bones of the skull and pelvis. When separation of the epiphysis occurs it is a fracture of the bone just beyond the line of junction, and the femur is the bone most often broken. With complete pseudo-paralysis and extension of the limb, the grating of the bone can be easily detected, as the manipulation of the part is not resisted.

The changes in the gums are characteristic, and are next to those of the bones in diagnostic importance. There is a tumefaction around the teeth and over those that are erupting. The gums are dark, bleed when touched, and may be so swollen as to protrude from the mouth. When the teeth have not been cut or the disease is not severe, a few hemorrhagic spots may be all that are to be seen. The breath is foul and the tongue coated in the cases with the swelling of the gums, but in the milder inflammation the tongue is often clean and the breath not disagreeable. The tissue around the teeth and over those that are oncoming is spongy and vascular. It is probable that the retention of particles of food, mucus, etc., causes a septic condition which gives the fetid breath, and produces in severe cases a necrosis of the gums and swelling of the palate. The gums are not swollen or inflamed in some cases where other signs of scorbutus are well marked.

Subcutaneous hemorrhages are frequently observed, and vary between petechiæ and the ecchymotic patches that are often mistaken for bruises. Ulceration may result. Usually the lower extremities and trunk show these changes best. Ecchymosis of the conjunctiva and the orbital tissues is a conspicuous symptom in some cases.

There are hemorrhages from the mucous surfaces; epistaxis and bloody discharges from the intestines are not uncommon.

Fretfulness and irritability are present early, and increase with the progress of the disease, until it is evident they are caused by physical suffering. The baby is tender when handled or touched, and cries with pain. The face has an anxious expression, which in severe cases is one of agony.

The skin is a dirty, "earthy" white or yellow, which is quite noticeable to nurses before the patient is supposed to require medical aid. Besides the hemorrhages that have been mentioned, there are papular and vesicular eruptions, which leave the skin harsh and dry. Perspiration is usually profuse.

Anæmia, wasting, and a general failure of strength are constant symptoms, but in fat rickety babies there may be a deceptive appearance of health.

The gastro-enteric tract is deranged; loss of appetite, vomiting, and diarrhœa accompany the disease, though they are not always persistent symptoms. The movements from the bowels are dark in color, contain mucus, sometimes blood, and are very offensive.

The abdominal viscera do not, in most cases, show signs of enlargement.

Catarrh of the bronchial tubes is common, due in many cases to the existence of rickets. Pulmonary hemorrhages, pneumonia, pleuritic and pericardial effusions, are found in debilitated and exhausted patients.

The urine often contains albumin, and at times blood is passed. It is probable that a greater number of cases would show evidences of kidney changes if it were possible to examine the urine during the acute stage.

The temperature range is not high, seldom more than 101° or 102° F. In a mild degree of scurvy it may be only a half-degree over normal. Inflammation or severe catarrh will, of course, increase the febrile movement.

The treatment of scorbutus is simple and has so little to do with drugs, that a brief mention of dietetic management is all that is required.

Give at once fresh milk, beef juice, and fruits or vegetables. Orange is liked by almost all children, and is greedily devoured. When orange does not agree or is distasteful, other fruits or vegetables will do as well.

The relief of the symptoms of scorbutus is so rapid under this regimen that medicinal agents are seldom needed, except as here indicated.

Local applications of evaporating lotions to the swollen parts seem to afford relief. An opiate is useful in allaying pain and irritability, and in checking severe diarrhœa. Stimulation is frequently needed to support the system. Iron is of service to combat the anæmia, but it does not hasten recovery if the dietetic management is neglected. Cod-liver oil and phosphorus are valuable in the cases where scorbutus and rachitis coexist. Sunlight, fresh air, and good hygiene are powerful aids to recovery. The fractured bones are to be treated mechanically until the anti-scorbutic diet has had its effect.

6 East Fifty-eighth Street.

A Medical Syndicate.—We read in one of the religious weeklies an enthusiastic notice of the adoption, by two churches in a town in Iowa, of a plan of assessing every church member fifty cents per month, and in return offering free medical attendance and $3 a week during illness, with the entire funeral expense in case of death.—*Polyclinic.*

Mrs. Amory's Bequests to Hospitals.—The will of the late Mrs. Jeanne P. Amory, of Braintree, directs the executors to sell within two years all her right, title, and interest in the real estate at 111 West Fifty-seventh Street, New York City, and to divide the net proceeds equally between the Massachusetts General Hospital in Boston, the City Hospital in Quincy, Mass., the Woman's Hospital, and the Skin and Cancer Hospital, both in the city of New York.

Preventive Inoculation for Cholera in India.—The method of preventive inoculation for cholera worked out by M. Haffkine in the Pasteur Institute in Paris, and applied extensively in India by the investigator himself, has been put to the test of actual experience near Calcutta. Dr. Simpson, the health officer, took special steps to make the inoculations made in the neighborhood of Calcutta to serve as tests of the efficacy of the method in man as severely scientific as possible. A telegram in the *Times* states that one of these tests has recently been completed. Of the 200 inhabitants of a native *bustee* (hamlet), 116 were inoculated with the protective vaccine. Not long afterward, an outbreak of the disease occurred in the hamlet; ten persons were affected, none of whom had been inoculated, and seven died. All those who had been inoculated remained free.

Progress of Medical Science.

The Treatment of Severe Albuminuria associated with Pregnancy.—In a paper read before the London Obstetrical Society, Dr. Herman concluded a valuable series of observations on albuminuria associated with pregnancy and labor. Every practitioner who observes his cases must have noticed that there are at least two main groups of kidney disease in this association. Albuminuria in a more or less marked degree is a very common complication of pregnancy, but in a large proportion, the majority, of the cases it does not lead to any of the graver symptoms to which pregnant albuminuric women are liable. In a certain number of such patients, however, not only is the disease acute in its onset and violent in its manifestations, but we get the dreaded eclamptic convulsions which threaten the life of the mother and jeopardize that of the unborn infant. The risks dependent upon the renal disease are, then—first, the life of the mother; secondly, that of the fœtus; and, lastly, the danger of the acute phase giving place to a chronic form of Bright's disease after delivery. The main points which still call for discussion are the means of distinguishing between the cases which are likely to comport a grave sequel and the best method of obviating the danger of usual defects and renal disease as a sequel. Dr. Herman tells us that the acute form attacks mainly women who are pregnant for the first time, and he points out that when the albumin in the urine consists mostly of serum albumin the prognosis is grave. It is, therefore, necessary for the practitioner to accustom himself to testing for the presence of paraglobulin as compared with serum albumin. One of the common symptoms associated with the albuminuria of pregnant women, as in albuminuria from other causes, is failure of vision, attributable to the presence of albuminuric retinitis, and possibly sub-retinal hemorrhages. In the graver cases this may go on to complete loss of perception of light. Although in most cases the cæcity passes off more or less when delivery has been safely accomplished, this is by no means always the case, and the preservation or protection of sight becomes one of the points to which treatment must be directed. Now, the treatment of the albuminuria of pregnant females is practically confined to the induction of premature labor. As soon as the uterus has been emptied, the symptoms usually promptly subside; indeed, the promptness of this subsidence is one of the most remarkable features of renal disease associated with pregnancy. The speakers, in the discussion that followed, accepted this conclusion, and did not hesitate to recommend that the uterus should be emptied forthwith in all really serious cases of albuminuria associated with pregnancy. The child is sacrificed, it is true, but its chances of survival in the presence of eclampsia, or even of severe albuminuria, are small indeed, so that this fact cannot and ought not to be allowed to weigh in the balance, especially as the mother is thereby rescued from one of the most terrible complications that can threaten the pregnant woman. Then, too, in the cases presenting indications of albuminuric retinitis. These are always severe cases, and most of them die if left unrelieved. Moreover, the further the case is allowed to go on the greater is the damage done to the delicate structures of the eye, and the greater are the risks of permanent impairment of vision. This is a serious point well worthy of consideration, and in future obstetricians will be well advised if they adopt the suggestion to empty the uterus as soon as, at latest, ophthalmoscopic examination reveals the familiar and easily recognized signs of albuminuric retinitis. There remains as an additional reason for adopting this course the fact that even in women who either do not have, or who survive, the fits, the kidneys do not always recover from the disturbance to which they have been subjected, and the patient not unfrequently remains the victim of chronic Bright's disease. On these grounds, therefore, severe albuminuria ought to be added to the list of indications for the induction of premature labor without waiting for the supervention of eclamptic convulsions before coming to a decision. This is not a specialists' question. It is one which any practitioner may be called upon to consider at any moment, and it is to be hoped, in the best interests of his patient, that he will henceforth recognize the extreme and manifold gravity of the risks attending the continuance of albuminuria in pregnant women.—*The Medical Press.*

Diabetic Neuritis.—Dr. Davies Pryce would distinguish two forms of this disease: 1, The motor or paralytic, and 2, the sensory or ataxic, the latter including Leyden's neuralgic group. He relates three cases of diabetic pseudo-tabes. (*The British Medical Journal.*) In all three cases, besides the ataxy, the knee jerk was absent. In Cases II. and III. the pupils reacted normally to light and accommodation, but in Case I. the reaction to light was sluggish. In Cases I. and II. sensation was affected in the feet and lower part of the legs, but in Case III. the feet only were involved. 1. A man, aged fifty-six, with diabetes and perforating ulcers of the feet, died in coma. The peripheral nerves of the right leg were examined and found diseased, especially the posterior tibial nerve, the lower part of which was thickened and embedded along with the atheromatous tibial artery in a mass of inflammatory tissue. Changes were also reported in the large anterior cells in the lumbar cord. 2. A man, aged seventy-two, had diabetes and gangrene. He had suffered from sciatica for ten years. A peculiar erythematous œdema of the feet was present at times. Changes were found in the anterior and posterior tibial as well as the sciatic nerves. Arterial disease was marked. 3. A diabetic man, aged sixty-two, also died of gangrene. The nerves and vessels were here also found diseased. In respect to the vascular disease, there was no evidence of rheumatism, alcoholism, or syphilis in the two last cases. The chronic course, the presence of ataxy, the absence of paralysis, the age (beyond middle life), the preponderance of sensory, vasomotor, and trophic symptoms, and the existence of arterial disease were the chief points in these cases. No relationship was apparent between the severity of the nerve symptoms and the amount of sugar present except that the erythematous œdema coincided with increased sugar excretion. The author does not think diabetic neuritis solely due to a specific toxic agent, but mainly to vascular disease and malnutrition. The posterior tibial artery is especially prone to degeneration, and the posterior tibial nerve supplied by this artery was chiefly implicated. Morphine and antipyrin were useful in allaying the pain. Operative procedure would, in the author's opinion, only have accelerated death.

Tachycardia in Pulmonary Tuberculosis.—Bezançon has published his views on the tachycardia occasionally observed in pulmonary tuberculosis. It is always a grave phenomenon. After it has persisted for a short period the heart begins to fail, the pulse becomes so feeble as to be uncountable at the wrist, and the patient suffers from dyspnœa, cyanosis, and œdema of the lower limbs. In some cases the tachycardia may be due to pressure on the pneumogastric by enlarged mediastinal glands, but this explanation will hardly apply to any cases except those in which the pressure is so great as to suspend completely the functions of the nerve. Slighter pressure might rather be expected to produce a slow pulse. Other cases may be explained by supposing a diminution in the calibre of the air-passages, since Marey has shown that by breathing through a narrow tube respiration becomes slower and the heart faster. But these explanations leave many cases unexplained. The author suggests that in them the hurried action of the heart may be due to certain toxins produced either by the bacillus tuberculosis or by the microbes (staphylococci, streptococci) of the secondary purulent infections so common in phthisis. Bouchard obtained from tuberculin a substance, to which

he gave the name of "ectastine," which produced dilatation of the vessels, and toxins with a similar property have been obtained from the products of the bacillus pyocyaneus by Charrin and Gley, and from those of the staphylococcus by Arloing. By acting as vaso dilators these substances would tend to produce tachycardia, since the heart tends to act more rapidly as the peripheral friction diminishes. In other cases it is possible that toxins may cause tachycardia by producing a neuritis of the vagus.—*Revue de Médecine.*

Arrested Growth of the Testes.—The term Eunuchoid is proposed for persons who have been found to be like eunuchs in all respects, except that in the former the testes, though small, are in the scrotum These persons have large frames, narrow shoulders, and broad pelvis. The face is beardless, the neck round and plump, and the voice is often high-pitched. The breasts are large, the penis and scrotum small, not being larger than they are in a ten-year-old boy. This condition of the testes is found in many idiots, and the arrest of development seems to take place in early life. In the *Journal of Anatomy and Physiology* Dr. Joseph Griffiths summarizes his study of two of these eunuchoids. The testes were small, and were found to be almost entirely formed of fibrous tissue, the seminal tubules being represented by fibrous rods with fissure like lumina containing atrophied epithelial cells. The testes were of normal shape, but the relative size of the epididymis was large. The tubules in most of the lobules of the globus major were normal, though in some lobules they were changed as if by a chronic inflammation. The prostate gland was small, tough, and fibrous. The glandular tubules were few in number, and these imperfectly developed. The seminal vesicles were small sized and empty. Both testes were affected, while in mumps followed by orchitis the inflammation is generally on one side only, and rarely destroys all the seminal tubules. When the testes lose their power of growth, from any cause, the patient develops at puberty, like a eunuch deprived of his testes in early life. Such a eunuchoid may have erections and ejaculations, but the secretion is devoid of spermatozoa, and the individual is sterile.

Operative Indications in Traumatic Stricture of the Urethra.—Drs. Legueu and Cestan gave the results of their observations on cases seen in the service of Professor Guyon. There were seventeen cases in the wards almost simultaneously. The lesion most often sustained is as follows: The ruptured portion of the urethra is usually on its lower wall, and the upper is either intact or else there is at least a strip of unruptured mucous membrane at this point. On this account operations are not to be done in these cases which contemplate a complete division of the canal. The obstruction in old cases comes at times from fibrous masses which are separated from the urethral canal by a less dense tissue, thus allowing of their removal without injuring the urethra. Excision *en masse* is to be avoided for the same reason. When there is no fibrous mass to be felt in the perinæum, then dilatation may be tried; but when they exist, then dilatation is only to be used as an adjunct to other measures. Internal urethrotomy may be done as a primary measure when dilatation is impossible, or it may be employed as a secondary measure after dilatation has failed. Internal urethrotomy is not regarded as curative, it being often followed by a return of the obstruction. In the milder cases in which the stricture is small in extent it sometimes succeeds admirably. In performing external urethrotomy when the wound is deep and it is impossible to find the urethra, one of two courses may be pursued: One is to allow the patient to recover and watch, when he urinates, where the urine comes from, and the other is to do a supra pubic cystotomy and retrograde catheterization at once. The latter is mentioned favorably. Resection of a part of the urethra and immediate suture are advised when the two parts are not separated too widely, too deeply situated, or too much surrounded by hard cicatricial tissue. In some cases a new urethra is constructed by uniting the sound tissues over a catheter. This is left in place three to five days. The surrounding callosities must all have been carefully removed and all granulations carefully curetted away.—*University Medical Magazine.*

Resorption of Bacteria into Recent Wounds.—According to the Berlin correspondent of the *Medical Press*, Hr. Schimmelbusch said that at the last Surgical Congress he had reported on experiments he had made on animals in disinfecting wounds infected by disease germs. The results were surprisingly unfavorable as regarded such attempted disinfection. In spite of making use of the most powerful disinfecting material, no results could be obtained. In the search for protective material, he had performed amputation, especially the tails of mice, shortly after infection, and had satisfied himself that even such amputations performed a few minutes after infection inoculations gave no result. From his observations he drew the conclusion that the micro organisms passed into the body juices with great rapidity and penetrated beyond the root of the tail in a very short space of time. In Bramann's klinik Niessen found that anthrax spores were demonstrable in the lymph-glands in them from one and a half to three hours after infection. The speaker had in later experiments attempted to ascertain in how short a time infective germs inoculated into wounds were found in the internal organs—liver, lungs, spleen, and kidneys. These experiments were carried out last summer. He had wounded mice at the root of the tail or on the back, had infected them with anthrax, and after a certain time had killed them. The minced organs were then either placed on a platter or implanted into healthy mice. After he had obtained practical evidence from three to five hours after infection he shortened the time of infection gradually, and found that in a large number of cases virulent anthrax bacteria could be demonstrated in the organs. The question now arose, did this happen in the pathogenic organisms only, or was it also the case with the saprophytes? In the case of rabbits killed five minutes after infection, he found after many experiments that numerous saprophytes were already present in the organs. As regarded plate cultivation, he remarked that it was necessary to take the whole or the greater part of the organs. Proofs of the presence of micro-organisms in the organs were never obtained when a few drops only were taken. At the first moment, the fact that such bacteria should be found within internal organs within such a short space of time appeared strange, but this fact alone gave an answer to the observation that amputation of the tails of mice a few minutes after infection was no longer of use. It was known that fatty emboli containing cinnabar did not take five minutes to reach the heart from the marrow of the bones. Resorption was naturally varied, according to the quality of the germs. In case of the excitants of sepsis, the animal was already lost even a few minutes after infection, and not to be saved by local treatment. Hr. Pfuhl was able from his own experiments to confirm the statements of the previous speaker. When wounds were from twenty-four to forty-eight hours old, however, and the germs were scattered over them, the animal was in many cases not infected at all. This fact was deserving of consideration. Hr. Schimmelbusch said he had paid a good deal of attention to old wounds, especially burns. Poisonous material was not readily absorbed from the superficies or from fascia. The receptivity also disappeared quickly from other wounds, probably in consequence of the formation of products of coagulation, which afforded protection. Burns also were not readily infected. He had never succeeded in infecting a cauterized wound. As regarded the disinfection of catgut, he said that in v. Bergmann's klinik it was disinfected in a one per cent. solution of sublimate, and that this solution rendered the disinfection perfect in one second, while hot air at 140° C. had no effect in two hours.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street

New York, June 30, 1894.

MURDER, INSANITY, AND THE MODERN JURY.

A FEW weeks ago a woman of this city, not previously considered insane, bought a pistol and went out and shot the mistress of her husband. She was examined by a commission and pronounced sane at the time of the examination. She was tried for murder and promptly acquitted, on the ground of insanity at the time of the act. The woman was related to a high police official.

Several months ago, a woman named Mrs. Halliday committed some horrible murders. She was tried at Monticello, N. Y., last week. The testimony showed that she had been three times confined in different asylums for insanity, and the superintendents testified that she is now insane. In fact, all the evidence of any moment was to the fact that the woman is insane. Her physiognomy and past history show her to belong to the lowest type of the mentally degenerate class. Despite the evidence, however, the jury brought in a verdict of guilty of murder in the first degree. Unless someone interferes, the demented creature will be killed by electricity in the approved and legal method.

The assassin, Prendergast, who shot the Mayor of Chicago, has also been practically pronounced sane and responsible by the marvellous intelligence of the modern jury.

The histories of the cases cited show how crude and illogical is our modern system of rendering justice, and how little attention is paid to those higher abstract principles about which one hears so much from our standard orators, and reads so much in our standard books.

It is agreed, theoretically, that an insane person is irresponsible and should not be hung or punished. This is also our law. Yet, when the crime is very outrageous, juries will promptly bring in a verdict of guilty against the evidence of experts, of experience, and even their own common-sense. On the other hand, a murder which appeals somewhat to their sense of justice will easily enable a jury to believe in the most transient and accommodating forms of insanity.

Now, if the juries are right in these cases, then the law and the ethics of to day are wrong. There is a direct conflict and antagonism which cannot be explained away. And we ought either to reform our law and admit that some lunatics are responsible, and some murders justifiable, or else reform our jury system into a condition of consistence with the theory of the schools and the practice of the courts.

THE DEATH-WOUND OF CARNOT.

THE death of the President of France by a stab of the liver is an instance of rare wound occurrence. We do not at present recall a similar case of fatal termination. Rupture of the liver from contusions and perforations of the substance of the organ by bullets are not very uncommon, but deep knife-wounds inflicted by an assassin are almost unheard of. It is quite evident that the wound in the case of the lamented victim was fatal from the moment of its infliction. The cablegrams state that the substance of the organ was penetrated, as shown by the autopsy, to the depth of five inches, that the aortic (evidently the cava ascendens) vein was wounded, and that two quarts of partly clotted blood were found in the peritoneal cavity. The distinguished victim died from the shock of sudden internal hemorrhage. Almost immediately after the thrust the mortal character of the wound was clearly indicated by the quick collapse. The futility of performing laparotomy for the arrest of such a condition was demonstrated by the results in this instance. It is still a question whether or not it is advisable to explore such wounds while the patient is in a condition of profound shock. If the hemorrhage from a wounded liver is of sufficient magnitude to induce rapid collapse, it seems quite clear that exploring the wound in the vain hope of securing a large vessel, only adds to the gravity of the situation by intensifying the shock and proportionally reducing the ultimate chances of the patient. If, on the other hand, the bleeding is small enough to be controlled by tamponing the liver substance, it will do no special harm if left to itself. It is quite probable, however, that the bleeding was very rapid, that syncope occurred very quickly, and that the hemorrhage had ceased of itself long before death. At the worst, it was a mercy that it was so soon over.

SUICIDE AND HEAT.

THE wave of heat which passed over this region last week caused excessive discomfort, and probably increased the mortality rate somewhat, especially among children. Quite a number of suicides were reported, and the ever-alert reporter has not failed to dwell on the current statements of the books, which show that suicide increases in hot weather and bears a definite relation to meteorological conditions.

A critical study of the statistics of Morselli and others does not furnish much support to the hot weather theorists. In this city, for example, the largest number of suicides occur in the spring, next in the summer; but the differences are not very great, being for eleven years 417 and 412, respectively (Ogle).

Furthermore, it is very doubtful whether the fact that more suicides occur in the hot weather, as stated by European statisticians, shows that the high temperature has a causal relation. The probability is rather that the climatic changes of the spring, by producing an increase of insanity, lead to suicide later.

A great deal of undue stress has been laid upon the cosmic influences leading to suicide. Many curious facts result from the manipulation of large numbers of statistics,

but it may be questioned whether the deductions made are often not merely coincidences. For example, it can be shown that more suicides occur in the last quarter of the moon and at the period of the year when the days are longest; also, that most suicides occur between 6 A.M. and 12 M.; that more occur in valleys than among mountains; and that there is in the east of Germany a "suicidigenous" area.

After all, however, it is the factors of race and civilization which are most important, the German race representing one extreme, the Scottish the other. In this country the foreign-born commit suicide oftener than the natives.

European statistics show a steady increase, both relative and absolute, in suicide; but in this city, according to Ogle's statistics, no such unfortunate tendency exists. The highest yearly rate up to 1880 was 1,805, when there was one suicide to every 3,017 inhabitants; the lowest rate was in 1864, when the ratio was 1 to 23,827. There has never been an epidemic of suicide in New York, though such phenomena have been reported in Europe.

News of the Week.

Dr. E. Allen Wood, of Pittsburg, died, on June 4th, of cerebral hemorrhage, in Philadelphia, where he had gone to attend the meeting of the Pennsylvania State Medical Society. He was born in Wood's Run, Pa., in 1834. He was the organizer of the South Side Medical Society, the oldest medical organization in Pittsburg, and had been president of that society, of the Allegheny County and of the Pennsylvania State Medical Society. He was also one of the organizers of the Western Pennsylvania Medical College, and was the first Professor of Dietetics in that institution. He served in the State Senate in 1875 and was instrumental in framing the Anatomical Dissecting act. In addition to his medical writings he was the author of several widely read novels, poems, and plays. He was a graduate of the Western Reserve Medical College in Cleveland. In 1859 he married Miss Lizzie Hopkins, of Brownsville, Pa., who survives him.

Myomectomy as a Substitute for Hysterectomy.—Dr. E. C. Dudley, of Chicago, writes: "In my paper with this title, read before the American Gynecological Society and abstracted in the MEDICAL RECORD of June 16, 1894, page 768, is a statistical error. The statement was made, that there had been no death in the past two years. There has been one death following this operation. The patient was atheromatous and over fifty years of age. During the first eighteen hours after the operation there were no unfavorable symptoms, when suddenly the pulse became imperceptible and death occurred almost instantly."

An Impostor.—Dr. Willis G. Tucker, registrar of the Albany Medical College, writes that during the last fortnight he has received inquiries from physicians in Lambertville, Keyport, and Perth Amboy, N. J., concerning a young man who has lost his left hand and claims to have been a student in the Albany Medical College. He gives the name of George, with different given names in different places, and is soliciting aid from physicians and druggists under various pretexts. He exhibits a letter of recommendation purporting to have been given him by Dr. Tucker, but the latter knows of no such man and says that there has never been a student answering to his description at the Albany Medical College.

Medical Protection in Rome.—The medical practitioners of the city and province of Rome have determined to form a "College" or association for the protection of their interests not only in their relations with patients, but against public authorities and hospital governing bodies. At a recent meeting of the Società Lancisiana, an elaborate report on the scheme, which has been for a considerable time in contemplation, was presented by Professor Sciamanna, and a provisional executive committee was formed to carry the proposal into effect.

A Biography of the late Sir Andrew Clark is to be written, with a preface by Mr. Gladstone.

Professor Gussenbauer, of Prague, has been chosen to take the chair of surgery at Vienna, occupied by Professor Billroth.

A Remedy for the Alleged Hardships of the Higher Medical Education.—In an address on higher medical education, before one of our State Medical Societies, the orator dwells on the alleged hardship to the student when he fails in his finals and says: "If the law compels a young man to study four years, it ought to give him some guarantee that he will be fairly dealt with. Were our medical schools compelled to refund one half the expenses of the student who fails to get his diploma (*i.e.*, one-half the cost of three years' maintenance and of three years' loss of time), if the schools were obliged to refund all moneys expended on lectures, the graduating class would not be reduced in numbers, but the ten per cent. that fail at their final examinations would have some redress." This is just the kind of a proposition that would be apt to strike favorably a certain class of legislators, and it would not be in the least surprising to see it, in the near future, embodied in "An act entitled an act," etc. Meanwhile, the *Journal* commends, to the author of the address under consideration, the following cold facts which have already appeared in these pages: In round numbers, there are upward of 118,000 doctors in this country, which, with a population, also in round numbers, of 65,000,000, gives an average of one doctor to every 550 men, women, and children; this population increases at the rate of about 2.5 per cent. per annum, but every year we add over five per cent. of new doctors. It does seem that we might worry along without making it any less "hard and unsatisfactory" to become a doctor, for the present at least.—*Journal of American Medical Association.*

The Progress of Surgery.—

TIME, A.D. 1870.

Scene: Surgical Ward.

Surgeon.—How is Jones doing?

House Surgeon.—Extremely well, sir: the wound is suppurating *nicely*.

Surgeon.—That's all right.

TIME, A.D. 1894.

Scene: The same as above.

Surgeon.—How is that amputation of the breast?

House Surgeon.—I'm sorry to say, sir, the wound is suppurating.

Surgeon.—What! Suppurating!!! *Do you say suppurating?* Well—I'm—— (Left gesticulating.)

Fable.—1. Under existing circumstances we deem it advisable not to point the moral.—*Medical Press.*

Officers of the American Medical Association.—The list of these, given elsewhere in this issue, shows a comparatively large number of names not widely known to the profession, and a deficiency of prominent members of the profession from the large medical centres of the East. This is likely to be the subject of unfavorable comment; and it has already been suggested that it indicates unfair discrimination; but such a view is not supported by facts. These prominent members of the profession were simply not present at the meeting, and, therefore, could not be chosen. Take the case of Philadelphia, which has been especially mentioned. Of the eight members present from this city, five either held official positions or were elected to them at this meeting, while, on the other hand, among those honored last year by important appointments, one who was to deliver a general address, two section officers, and six members of the general business committee, failed to attend the meeting.—*Philadelphia Polyclinic.*

The Polyclinic does not tell quite all. The State of New York contains one-tenth of the medical profession of the country, including a good many men who might be called leaders. But the State is practically disfranchised, because its State Society has no Code but that laid down in Holy Writ.

Small-pox in Chicago is Decreasing.—During the first seven days of May 162 cases were reported; during the first week of June, only 50 cases. At present there are less than 350 patients in the small pox hospital. The deaths from small-pox for May numbered 290. Over 500,000 vaccinations were made during the month. The entire city has been gone over once and a portion twice. Much of the opposition to vaccination, which has been so strong in the foreign quarters of the city, has been overcome by the courage and tact of the physicians in the Health Department.—*Chicago Medical Recorder.*

A New State Hospital for the Insane, under homœopathic management, is to be established on the Collins Farm, thirty miles distant from Buffalo.

New Asylums in New York.—The State Custodial Asylum, at Rome, N. Y. (formerly the Oneida County Almshouse), an institution for the care and treatment of imbeciles and idiots, has begun its work in the field by relieving some of the State Hospitals of patients of that class.

The Prevention of Tuberculosis.—The Pennsylvania State Board of Health, at a recent meeting, adopted the following timely resolutions:

Resolved, That it is the sense of the State Board of Health of Pennsylvania that the time has come when the State should provide hospital accommodations for persons suffering from pulmonary tuberculosis in the case of those who cannot be properly cared for in their own homes, and who through carelessness might be dangerous to the community at large. It is believed that the establishment of such hospitals might be of great value in educating the people.

Resolved, That it is the sense of the State Board of Health of Pennsylvania that all inmates of prisons, reformatories, almshouses, hospitals, schools, and other public institutions be vaccinated immediately on admission.

This action is in the spirit of progressive and preventive medicine, and should be the precursor of legislation looking to the enforcement of the views so well expressed.

New Railroad Hospitals.—It is reported that the "Big Four" railroad will establish hospitals at Cincinnati, Columbus, Cleveland, Sandusky, Peoria, Kankakee, Cairo, St. Louis, and Indianapolis. To support them, each employee with a salary of more than $50 monthly will be taxed 50 cents per month.

Medical Cabinet Officers.—The New French Cabinet includes two representatives of the medical profession among its members. Dr. Viger retains the portfolio of Minister of Agriculture, which he held in the last ministry, and Dr. Lourties has been appointed Minister of Commerce.

Consumptive Hospital for Baltimore.—Baltimore is trying to establish a hospital for consumptives. A meeting of medical men and others interested in the project was held on May 15th.

An American Doctor a Mandarin.—Dr. William H. Park, a medical missionary and surgeon in charge of the Methodist Hospital at Soo Chow, China, has been given the rank of mandarin. The honor was bestowed on account of Dr. Park having successfully treated a Chinese general for his wounds.

Vaccination Test Cases.—Last week (Saturday) Judge Bartlett, of the Supreme Court, issued an order to show cause why writs of mandamus should not be granted to compel the principals of public schools to allow the children to attend school. The children were excluded from the schools on the ground that they were not vaccinated. The parents refused to allow them to be vaccinated. The cases are brought under the advice of the Anti Compulsory Vaccination League.

The American Association for the Advancement of Science will hold its next annual meeting in Brooklyn during August. Brooklyn citizens have raised $5,000 to defray the expense of entertaining the scientists. This sum, we believe, is nearly as much as that given by the American Government to entertain the Pan-American Medical Congress.

Yellow Fever has not yet made its summer appearance in this country, but several infected vessels have been quarantined in Florida ports.

A Number of Colored Physicians of Baltimore have decided to organize and open a hospital and dispensary. A building has been secured, and in a few weeks the work will begin.

The Sale of Patent Medicines.—There is a lively war in England just now between the apothecaries and grocers over the sale of patent medicines. The druggists, suffering from competition, have prosecuted the grocers for selling poisons without license. The latter dealers are retaliating by all manner of prosecutions for technical violations of the pharmacy laws.

A Small Small-pox Epidemic has been found in Staten Island.

Modes of Cholera Propagation.—A correspondent of the *British Medical Journal*, in looking over his note-books recently, found the following, written in 1870 by a medical contributor of the *Bombay Times*:

Surgeon-Major Bryden's View.

"Earth grown, wind blown;
Air and vapor hatch'd and sown;
Thus the pest o'er earth has flown."

E. N. Macnamara's View.

"Man bred, man shed;
Anon diffused in watery bed—
Multiplied and further spread;
Thus the pest o'er earth has sped."

Bryden's view was "wind-blown" farther than its subject; it lived long, despite Macnamara's demonstrations of its fallacy.

New Asylum in Maryland.—The recent Legislature of Maryland passed an act to erect a $75,000 insane asylum for the better care of the insane of the State.

An Insane Human Ostrich.—An interesting operation was performed recently at the Lancaster County Lunatic Asylum upon William Fitzpatrick, one of the inmates. This man, some time ago, took to swallowing things, and on one occasion he ate one hundred and ninety-two flooring nails, which naturally upset his digestion. During the operation, which lasted two hours, the surgeon took from his stomach the one hundred and ninety-two nails aforesaid, varying from one and one half to three inches in length, a half of a screw, a piece of wire, two buttons, and a mass of matted hair. The nails alone weighed nearly two pounds.

We are Quite in Sympathy with our esteemed contemporary the *New York Medical Journal* in its remarks about the unnecessary and at times grotesque nudity of medical photographs. But why does our esteemed editor publish in a subsequent issue such startling examples of genital exposure.

The Chinese Plague.—From Hong Kong reports concerning the plague are very discouraging: thirty-five deaths occur daily, and the malady is spreading to all parts of the native city, and now threatens the foreign quarter. The slaughter of pigs has been prohibited, as well as the catching of fish, for fish are said to be infected by the disease. So virulent is the plague that many have been struck down as they were being borne through the streets in sedan chairs.

Ontario Medical Council.—At the annual meeting of the Council of the College of Physicians and Surgeons of Ontario, held at Toronto on June 12th and four succeeding days, the following named officers for the ensuing year were elected: D. L. Philip, Brantford, president; William T. Harris, Brantford, vice-president; Robert A. Pyne, Toronto, registrar; William T. Aikins, Toronto, treasurer. Executive Committee—The president, vice-president, and Dr. Campbell, London, Ont.

Taxing Physicians.—The city of Louisville, Ky., taxes each physician $10. Charlotte, N. C., also taxes medical men to the tune of $15 a year. Thus the former city secures an annual income of $3,400, and the latter $405, and yet it is expected and demanded of medical men in both of these cities to give a large share of their time and skill to public institutions and charity. Why are not lawyers and clergymen taxed as well? It would seem fully as appropriate.—*Medical Age.*

The Journal of the American Medical Association publishes this fortuitous combination of items:

"The American Academy of Medicine will meet in Jefferson, N. Y., August 29th and 30th."

"℞. In debility from seminal losses, elixir nutrans, ℥ viij. Sig. Dessertspoonful four times a day, after meals and at bed-time."

The British Medical Association will hold its sixty-second annual meeting in Bristol, on Tuesday, Wednesday, Thursday, and Friday, July 31st, and August 1st, 2d, and 3d, under the presidency of Dr. George Hare Philipson, of Durham. Among the Americans who are announced in the *British Medical Journal* to take part in the proceedings are Dr. J. J. Chisolm, of Baltimore, and Dr. George T. Stevens, of New York.

The International Medical Missionary Society is again at the front, and announces plans for a $250,000 building for the purpose of educating medical missionaries. We have the utmost sympathy with the medical missionary movement, but we cannot see the least use for a special college in order to educate this class of persons. The medical missionary, if he expects to do creditable work, must receive a good medical education, and there are abundant opportunities in this city and elsewhere for the purpose.

The Society of Physicians and Naturalists of Germany hold their sixty-sixth anniversary in Vienna from the 24th to the 30th of September next. Among the many who will take part in the celebration may be mentioned Professors Helmholtz and Leyden, of Berlin, and Forel of Zurich. The sections into which the ordinary business of the society is divided will on this occasion be headed by Viennese *savants*, such as Gustav Tschermak (Rector of the University), Nothnagel, Wiederhofer, Krafft-Ebing, and Politzer. For the expenses of the celebration the Austrian Government has voted 10,000 florins; while the municipality gives a grand reception on the 27th. A ladies' committee, organized for the entertainment and general convenience of their foreign sisters, is already working in co-operation with the central committee; and no effort will be wanting to make the anniversary worthy of the noble society whose sixty sixth birthday it commemorates.

The New Outcrop of Cholera Abroad simply confirms the record made last fall, at the meeting of the American Public Health Association by members who had been in correspondence with Continental, English, and Canadian health authorities. Owing to the many foci established by the disease last year, in Europe, a sharp recrudescence was to be expected. Now it remains for the health authorities of this country and Canada to be on the alert for our common enemy. The Canadian quarantine station at Grosse Isle is reported as being in perfect order, in reality one of the most extensive of modern plants. The island is in the St. Lawrence, below Quebec, in an ideal situation. There are forty buildings, and in case of necessity three thousand persons can be housed. The effects of one thousand immigrants can be scientifically disinfected in twenty-four hours. Dr. Montizambert is in charge. The government of Canada has named him Superintendent of the Canadian Quarantine System.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, April 23, 1894.

SENECA D. POWELL, M.D., PRESIDENT, IN THE CHAIR.

Advertisers Admonished.—The Comitia Minora, having received a report from the Committee on Ethics with regard to advertising by certain members, had, in accord with the report, admonished the offenders.

Registration of Births.—DR. DANIEL LEWIS called attention to the faults of the bill before the Legislature relating to the registration of marriages and births, and offered a resolution recommending its amendment so as to make it obligatory upon parents, instead of upon physicians, to report births to an officer, similar to the manner in which it was done in England, the records to be such as shall be admitted as evidence in courts of law. The resolution was adopted.

Brown-Séquard's Methods.—DR. PAUL GIBIER, in a paper with this title, outlined some of the more important work accomplished by Brown-Séquard, and then passed to his introduction of animal extracts in therapeutics and physiological study. His discoveries with relation to the nervous system were of a character, Dr. Gibier thought, to prevent his name falling into oblivion. His investigations into the action of the animal extracts had not been limited to the testicular fluid in rejuvenating the aged, as some had maliciously suggested. It was no credit to certain physicians high in the profession that they had not even mentioned his name when writing upon the thyroid extract in the treatment of myxœdema.

Dr. Gibier then passed to his own experience with the animal extracts in the treatment of locomotor ataxia, cancer, paralysis agitans, and other affections, in all about twenty-two cases. The extracts usually employed were testicular, pancreatic, or nervous, or a combination of these. In this list he did not include cases of epilepsy treated by cerebral extract. In two cases of cancer, one of the breast and one of the uterus, there had been improvement of the general health, and in one cessation of hemorrhage. In two cases of diabetes there had been diminution of the sugar and general improvement. In at least two cases of locomotor ataxia of marked degree, the bladder and intestines being involved, there had been great improvement in the ataxia and other symptoms. In one case of bulbar paralysis, sent him by Dr. C. L. Dana, the respiratory and cardiac symptoms and dysphagia had threatened soon to terminate life, but under large hypodermic doses of testicular and nervous matter the man had returned to about his former healthy state. The difference in result from the same treatment in apparently similar cases led Dr. Gibier to remark that there probably was a difference in the pathological lesions not yet recognized in the classification of the cases.

Scorbutus in Infancy.—DR. WALTER LESTER CARR read the paper (see p. 811).

Adds Cream to Cow's Milk.—DR. JOSEPH E. WINTERS never knew scorbutus to be mistaken for any disease except rheumatism. The baby should be examined when asleep. There was no possibility of any baby being properly nourished on condensed milk or any artificial food on the market. Even cow's milk would cause scurvy if after the proper dilution cream were not added to bring the proportion up to four per cent. In other words, when the casein had been reduced sufficiently so that it could be digested by the stomach, one should add cream.

DR. HENRY KOPLIK made some remarks upon the nature of scorbutus, whether it was an infectious disease and whether related to rickets. He thought it was independent of rickets.

DR. CRANDALL thought statistics of the frequency of scorbutus were liable to be deceptive if based solely on dispensary records, for the class of people who visited dispensaries were likely to give their babies the freedom of the table, or such a variety of food as would prevent scurvy, whatever else it might lead to. The large majority of reported cases had occurred in private practice.

DR. CARR, in his closing remarks, said the rapidity of recovery was much greater when the patients were given fresh fruit and fresh food.

Paludism in Children in New York.—DR. H. D. CHAPIN read the paper. The rarity of paludism in New York rendered the subject somewhat difficult to deal with. He had seen fourteen cases in children, at the Demilt Dispensary, the past eighteen months, the diagnosis having been confirmed by finding the plasmodium in the blood. The oldest of the patients was about thirteen years of age, but most of them were much younger. Fever was the chief manifestation, and it was often difficult to make out the distinct periodicity mentioned in the books. The tendency of the disease in the city was toward spontaneous recovery. It responded to quinine. It was most frequently mistaken for catarrhal condition of the intestinal tract. One case had been diagnosed tuberculosis. A certain form of rheumatism sometimes simulated malaria, so also a mild form of typhoid, or a condition arising from bad feeding and foul air; but here the plasmodium was absent.

A communication which Dr. Chapin had received from Dr. Osler, of Baltimore, stated that out of 240 cases of malaria seen at Johns Hopkins, only 17 were in children. Dr. Osler had learned to place more and more reliance on examination of the blood in diagnosis.

Relies on Examination of the Blood.—DR. HENRY KOPLIK thought the plasmodium was unmistakable, and examination of the blood was so easy that there should be no excuse for not making a correct diagnosis. In his cases there was, as a rule, no distinct chill, but a chilly sensation. In all of them the malaria had been contracted outside of the city. No reliance could be placed upon a large spleen in the diagnosis of malaria in infants. If quinine were given before examining the blood, the plasmodium would probably not be found.

DR. W. L. STOWELL thought poisoning by bad air was frequent in the city, but not by the plasmodium of malaria. The majority of children said to be suffering from malaria were set all right by a cathartic and stomachic. He referred to an English work which conveyed the impression that malaria was one of the chief diseases in New York City, whereas it was very rare. All cases with the regular symptoms of the diseases seen by him had come from without the city.

DR. CHAPIN, in closing, remarked that he thought the term paludism a better one than malaria, since the latter meant bad air, of which we certainly got enough in New York, but it did not produce the plasmodium.

Changes in the Medical Department of the University of Virginia.—Dr. William Christian has been elected to the Chair of Anatomy, and Dr. J. Staige Davis Adjunct Professor of Pathology and Hygiene.

New Surgical Hospital for Newport.—Mrs. F. W. Vanderbilt has given to the Newport Hospital corporation a large sum of money, and plans have been made for a building for surgical purposes. It will be known as the Vanderbilt Surgical Building, in honor of its donor, and will be of brick and iron, 52 by 36 feet. It will have an accident-room, operating-room, and etherizing and other necessary apartments.

The Tragic Side of Medical Life.—Another name has to be added to the ever-growing list of medical martyrs to professional duty. Dr. A. L. Copner, of Ilfracombe, England, has died of diphtheria, contracted while in attendance on a child suffering from that disease. The child refused to take any remedies, and when it was sought to apply medication directly to the diseased parts by means of syringing, struggled and coughed, bespattering Dr. Copner with infective marerial.

Correspondence.

OUR LONDON LETTER.

From our Special Correspondent.

CLINICAL SOCIETY CONCLUDES THE WORK OF THE SESSION —ANNUAL MEETING—PANCREATIC CYSTS IN DIABETICS — PURPURA AND PEMPHIGUS TREATED BY SULPHO CARBOLATES—ULCERS OF LEG TREATED BY CHLORINE—THE QUEEN'S BIRTHDAY HONORS—THE "NOBLE PROFESSION" IGNORED—GENERAL MEDICAL COUNCIL—WARNING DELINQUENTS—SCOTTISH UNIVERSITIES AND THE CURRICULUM—AN IRISH SQUABBLE—THE DENTISTS AND THE COUNCIL.

LONDON, May 31, 1894.

ANOTHER society, the Clinical, has concluded its work for the session. The annual meeting was held on Friday last, when the office bearers for the ensuing year were elected and other routine business transacted. It was agreed in future to devote three whole evenings each session to the exhibition of living specimens—these exhibitions having proved very attractive. The same evening ordinary work was also carried on which I will briefly report.

Dr. Churton gave an account of a case of pancreatic cyst which formed in a diabetic patient, a man, thirty-five years of age. He applied for pains in the abdomen and back, and complained also of rumbling in the bowels. The epigastrium was prominent, and the pyloric third of the stomach, evidently pushed forward by a tumor behind it, splashed on palpation. The whole left hypochondrium was dull. The transverse colon was separated from the stomach by a dull area of varying width. The urine contained sugar; its specific gravity was 1.033; its quantity was not yet markedly increased. The patient had become mentally and physically rather slow and weak: his face and lips were pale. Had never had any abdominal injury. Exploration in the eighth left intercostal space in mid-axillary line, found fluid of a dirty olive color, containing very little ordinary albumin. A slight circumscribed peritonitis followed the puncture on its subsidence in a few days; an incision was made in front by Mr. Ward, who drew off the fluid through a trocar, and then, having enlarged the opening in the cyst, passed his finger through the cavity to its posterior wall below the last rib, made an incision at that part for drainage, and closed the cyst and the wound in front. Patient was treated with pancreas extract, or liq. pancreaticus, and various kinds of diet, including grapes, one-third of a pound daily, which appeared to considerably increase the quantity of sugar in the urine. In February there was a trace of acetone in the urine. In March the discharge from the sinus, which had been clear and watery, became again purulent, but remained small in quantity until September, when it was increased, and there were signs of reaccumulation of pus behind the stomach, and purpura appeared on the feet and legs. For two or three months he had been an out patient and insufficiently fed. Sinus was enlarged, liberating much pus; but the suppuration afterward, in spite of further incisions, spread behind the peritoneum, invaded the ureters and kidneys, and the patient died on January 7, 1894. On autopsy the pancreas was a mere mass of fibrous tissue in which no trace of gland tissue could be discovered by the microscope. In the duodenal end there was a very small cavity, apparently the remains of a former cyst. There was no calculus. Surgical opinion seemed to favor incision of pancreatic cysts rather than aspiration; but the author, instructed by the present instance, considered aspiration preferable in cases associated with glycosuria, since—1, the glycosuria is a sign that the pancreas has become atrophied; 2, that being so, it does not appear that life can be much prolonged, even with the aid of pancreas extracts; 3, diabetic patients are more likely to become a prey to septic organisms; 4, pancreatic cysts have been cured by aspiration; 5, in eight successful cases treated by incision to which the author had been able to refer, glycosuria was not present; 6, he had not been able to find records of any successful cases in which it existed.

The president, Mr. Hulke, observed that stress was laid usually upon the nature of the cyst contents in arriving at a diagnosis, but though this might possibly be of some value in new cysts it did not hold good of older cyst formations. For operative purposes he divided these cysts into two groups: First, those which were stalked and connected with only a small portion of the pancreas. These could easily be drawn up and drained. Secondly, those which were more or less sessile, and these were much less easy to deal with. Mr. A. Gould considered aspiration of these cysts a rather dangerous proceeding, and had never done it himself; but having opened three such cysts, in addition to having assisted at the opening of another, he said that in every instance he was thankful that he had not attempted aspiration, for it would in every case have exposed the patient to the risk of wounding one or more of the large vessels running in front of the cyst, the stomach, or the duodenum. He pointed out that the contents of such cysts were usually too thick to come away freely through an ordinary aspirator, and he repeated that the aspiration of abdominal cysts was unnecessary and dangerous. With reference to the indication afforded by concomitant glycosuria, he suggested that in the presence of marked glycosuria it would be preferable to let the case alone. Such cysts, moreover, refilled with great rapidity, and no one would regard repeated aspiration as a safe or desirable practice.

Mr. Wallis concurred in this view, and in one instance had seen alarming symptoms follow aspiration.

Dr. Churton, in reply, said he only looked upon aspiration as a *pis aller*. He had been very much impressed by the failure of the operation in his case, especially as such patients were peculiarly liable to take on septic changes. He pointed out that hydatids were sometimes cured by a single aspiration, and in most text books it was stated that in certain instances cysts of the pancreas have likewise yielded to a single puncture. If this were so, then he thought it was worth trying. If, on the other hand, aspiration always failed to afford permanent relief in diabetic patients, he agreed that it would be better to leave such cases alone.

Dr. Sansom then related a case of purpura hemorrhagica with acute pemphigus, probably induced by influenza, treated by half-drachm doses of sodium sulphocarbolate every four hours, and terminating in recovery, in a girl, aged twelve. He referred also to a second case, equally successful.

After this Dr. E. Diver explained a plan of using chlorine gas in the treatment of chronic ulcers of the legs, and related two cases. The gas was formed by pouring on about two drachms of potassium chlorate, ʒ j. or more of HCl, in a pickle or marmalade jar, the outside of which was covered by brown paper. After this a disk of white paper was introduced, and on top of the paper a sufficiency of absorbent wool; a large cork was then fitted to the neck of the jar. The wool, yellowish green on the surface when at first exposed to view, was then placed over the ulcer in each case and quickly covered by a gutta percha tissue: then the patient was left to bandage the leg as accustomed to. No rest was enjoined. The gas was probably chiefly Cl, with some peroxide of Cl in mixture. He had been led to try chlorine gas by observing the extraordinary way in which it increased the germinating power of poor samples of barley. This had induced him to try it as a stimulant in these two cases.

LONDON, June 2, 1894.

The Queen's birthday has passed with the usual list of honors conferred on the occasion, but the recognition of medicine is as slight as usual. Professor Grainger Stewart is knighted, a distinction by no means equal to his professional fame, and which may be looked upon as merely a mark of his court position—physician to the

queen in Scotland. The same distinction has been conferred on Mr. Seymour Haden; but this, too, not as a medical man but as the President of the Society of Painter-Etchers. Dr. Bucknill also receives a knighthood, again not for his medical work, which has been great, but in recognition of the fact that he was the originator of the Volunteer force in 1852. He would probably have been passed over even now, but that his brethren and admirers have lately determined to show him honor in his old age, and to place the fact of his service to his country in initiating the Volunteer force beyond historical doubt. So the opportunity of official recognition has at last been taken. It is the usual thing where a man who has done something is "only a doctor." Either his claim is passed over altogether or until forced recognition in old age makes it worthless. Liberal governments have generally been most illiberal to the profession. It is very well for Mr. Gladstone to come to the Andrew Clark meeting and make a fine speech about the "noble profession;" but in all his years of power what has he done to recognize its nobility? True, he gave a baronetcy to Clark, his own devoted doctor, and he knighted Foster for his electioneering services. But such left handed recognition deserves the contempt rather than the gratitude of our "noble profession." Bucknill has reaped all the honor his brethren could give before his public services were noticed. Dr. Russell, the Lord Provost of Edinburgh, has also been knighted, and similar criticism might be made. He has never engaged in private practice, but his services to Edinburgh and his authority on questions of public health are well known. Some other honors conferred on army and navy surgeons, and those in colonial public positions of importance, read the same lesson as to the value set on medicine by our politicians. Had either of the above been a brewer or distiller, the present government, notwithstanding its so-called "temperance" leanings would undoubtedly have followed precedent and made him a lord at the very least.

The General Medical Council extended its meeting over six days. I last week sent you an account of the chief subjects discussed and have now only to supplement that with remarks on the later proceedings. A good deal of time was consumed in the amendment or regulation of the penal procedure. The Council seemed desirous of postponing a sentence or of receiving evidence after it had given its verdict, but wisely took the advice of its legal assessor and ultimately adopted his suggestions. The question came forward on three separate days—on one it was said the object was to meet the case of young men who had recently passed and had been entrapped into the offence of "covering" unqualified men by ignorance as to the Council's rules. This is certainly a very poor case, for young men fresh from the schools are not at all likely to be so simple as not to know that this offence is infamous in the eyes of respectable men as well as dangerous to the perpetrator. If there were any doubt as to the knowledge of the young men, let the Council order the Registrar to hand to every one of them a statement of the law with the receipt for the registration fee. Such a statement as to the conditions on which they would be permitted to remain on the register might very well be printed on the receipt itself. The Council has determined to advertise a warning in the medical journals.

The Scottish Universities Commission having framed an ordinance under which some persons might evade the five years' curriculum, the President called their attention to the matter. Probably the Council will have to represent the matter to the Privy Council. It is most important that the curriculum should be enforced in all cases alike, and the Scottish universities must not be allowed to interfere with it.

The Dublin Apothecaries' Hall was attacked by the College of Physicians backed by the Education Committee and the Inspectors of Examinations. The College of Surgeons of Ireland formed a conjoint board with the apothecaries, as well as one with the Dublin College of Physicians, which wants to keep medicine in its own hands. *Hinc illæ lachrymæ.* To be sure there is no denying that the Dublin Hall is the weakest licensing body in the three kingdoms, and the representatives of its college rival would gladly see it abolished. It could very well be spared from the long list of rival bodies, but then so too could any one of the others. Indeed some of us would not object to make a clean sweep of them all, and the Council too. But the Hall has legal rights and the delegates of the other vested rights could not agree to represent its deficiencies to the Privy Council and ask for its suspension. In its thirty-five years of existence the Council has not once taken this extreme step, and so delay was urged for this reason after repeated assurances that every recommendation will be carried out. The Hall has had a narrow escape, partly perhaps due to a fear that the process of suspending corporations, if once begun, might go merrily along, *i.e.*, to the profession, though sadly to corporations. In that case this Irish squabble is worth pondering.

The dentists are to receive a warning about advertising as "easily carried so far" as to bring them under the penalty of "infamous conduct." The dentists asked to have a representative of their own on the Council, which has no power and no desire to appoint one. The best plan for the dentists would be to influence one of the colleges which grants dental diplomas to nominate one of its alumni as its representative on the Council. There are dental scientists who are also fully and even highly qualified surgeons also. Let the dentists try and they will at least learn something of the force of college exclusiveness. The office-bearers want all the emoluments, all the honors, all the loaves and fishes to divide among themselves and have nothing to spare for outsiders.

MEDICAL NOTES ON THE WRECK OF THE KEARSARGE.

To the Editor of the Medical Record.

Sir: At the request of a number of my friends, and with the hope that other medical men might be interested, who mayhap do, or do not go down to the sea in ships, I have ventured to recall certain disjointed bits of observation made recently during the night of the wreck of the Kearsarge, and during the nine subsequent days that the ship's company remained on a desert coral island in the Caribbean Sea.

The ship struck on Roncador Reef, on February 2d, at about seven o'clock in the evening, just after dark. All possible efforts to get the ship off had proven vain, and an order was passed to all departments to make ready for abandoning the ship, when that should become necessary.

The surgeon's duties were to bring the sick into a safe place, to save and preserve the medical records of the ship, to select from the medical stores the medicines which would be of most use in emergencies, to carefully guard the distilled liquors, and superintend any necessary issue of the same, and to be prepared to render immediate medical or surgical assistance where needed. After all these things were attended to, it became our additional duty to prepare convenient packages of medicine for each boat. These packages contained a half litre of brandy, or whiskey, a hundred 0.2 gelatine-coated quinine pills, about sixty grammes of Squibb's mixture, a bottle of tablet triturate cathartic pills, and a couple of roller bandages.

Happily the accidents which occurred during the night of the wreck, though numerous, were largely of the nature of simple abrasions or contusions; only one case of an incised wound occurred, produced by the slipping of an axe while some rigging was being cut away, the axe entering for about an inch into the calf of a man's leg. Another man was caught in a bight of rope, one end of which was attached to a gun, as it was being "hove"

overboard. He was thrown forcibly against the side of the ship, striking his chest and head; but upon application of restoratives he soon recovered consciousness, and in a few hours was none the worse, apparently, for his shaking up.

There were but three on the sick-list proper at the time that the wreck occurred. One was an apprentice, slowly recovering from a keratitis of traumatic origin; one a case of incipient phthisis complicated with a syphilitic inguinal adenitis, which rendered walking difficult; the third was an old mulatto seaman, who, in virtue of a mitral lesion, a chronic nephritis, with albuminuria and œdema of both legs, promised to soon be of more use to some pathologist than to the naval service. The keratitis patient was one of the first to spring into the water on the morning following the wreck—of course minus his occlusion bandage; and yet his corneal lesion continued during the ensuing days on Roncador Cay to decrease in size, and to heal, notwithstanding exposure to bright sunlight and the lack of appropriate treatment. The old seaman went over the side, hand over hand, down a rope for a distance of twenty-five feet or so, as did every one else, and then, with two men to support him, he waded for a mile and a half through water up to his neck. The rest of the way he was able so secure a place in one of the boats. Although fearfully exhausted on his arrival at the little island, and very near collapse, he pulled through nicely in a few days, and is now, though still at the Naval Hospital in Brooklyn, better than he has been for a long time.

During the long night of the wreck the doctors, from their coigne of vantage by the emergency outfit, the sick, and the medical stores, were able to study, among other things, examples of the psychology, expression, and even the therapeutics of fear. For example, an unemployed man, perhaps wearing a life preserver (!), and having several fathoms of rope around his waist, would come to us, and with wide-open, staring eyes and pale perspiring countenance, ask, in a voice made weak by some constriction in his throat: "Doctor, do you think we'll have to swim for it? How far off is land?" With the assurance that land would be seen at daylight, only a couple of miles off, accompanied by the gift of a cigar and a light, the "patient" would take two or three deep whiffs, and go away entirely cheerful. Very many times did we make the confirmative observation that night of the peculiar effect of tobacco in calming the nervous paroxysm produced by the unfortunate combination of dread, suspense, and inaction. Another, by no means new, observation, was the enormous rise in spirits and courage produced in every one, during the long pull from midnight to daylight, by a plate of beans, some crackers, and black coffee without sugar, which at other times would hardly have been a satisfying repast. Thus, even at night, in a shipwreck, a full stomach, and the beneficent effect of that by some abjured poison, assisted us all very materially in facing difficulty and danger and in going forward with a calm, unflinching courage to meet whatever might occur. What better argument does the smoker want?

In anchoring lines and directing the transfer of men, food, and water, from the ship to the island, a number of officers were compelled to remain in the water up to their waists from daylight until about three in the afternoon, with an intense tropical sun beating down on their heads, after the preceding night of hard work and anxiety. This caused temporary nervous collapse in one case only, and a woollen blanket (the only one we had), two hours' sleep, and a couple of ounces of brandy, were all that was necessary in the way of treatment.

In order to dry outer clothing for the purpose of having sufficient covering for the night, a great many arms, legs, and necks were exposed to the afternoon sun. In upward of a hundred and fifty cases dark red belts of sunburn quickly appeared, which toward morning developed as burns of the second degree. Linseed oil and lime-water were applied three times a day with great relief, and before a week had passed one could peel off great sheets of epidermis from the arms, legs, or face of almost any one. On account of the fierce rays of the sun it became necessary to issue a prohibitory order to the men, to prevent unnecessary exposure, between the hours of eleven in the morning and three in the afternoon. Those who were compelled to remain out wore a sort of "puggaree," improvised out of a handkerchief, in order to protect the back of the neck.

In regard to water and food: Brackish water was obtained from a well dug in the sand, and it was very welcome, inasmuch as only two hundred and fifty gallons of ship's water had been saved, to last two hundred and three men for an indefinite period. Some mouldy bread made the only starchy constituent of a diet composed of canned meat, sea-birds, and fish. Sleeping arrangements were confined to little hollows in the sand for each individual, and the protection from dew afforded by overturned boats or rough-and-ready tents of driftwood and pieces of sails. Latrines, in form of trenches, were constructed at the extreme end of the island for the disposal of excreta, and these trenches were about a thousand feet from the camp.

With all this exposure only two or three took slight colds, and no case of rheumatism or of diarrhœa or indigestion developed. All abrasions and cuts healed rapidly in that germ-free air, and, without even needing a dressing, frequently. It would be interesting to know exactly to what extent the constant trade winds affected the hygiene of the place. That out of two hundred and three men no resultant illness should have occurred is truly remarkable and well calculated to exemplify the adaptability of the healthy human organism to almost any environment. In fact, it is my belief that this temporary reversion to primeval modes of living did all of us more or less good physically.

In conclusion I should like to note that the tablet-triturates which are issued to the naval service deserved the highest praise. Those in properly corked bottles went without injury through the severest test of exposure to moist air and to water. They were particularly pleasing and convenient, where no other means for weighing or compounding were at hand. The gelatine-coated pills all became sticky from the moisture of the air, and so were rather difficult to handle.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 23, 1894.

	Cases.	Deaths.
Tuberculosis	83	81
Typhoid fever	[illegible]	3
Scarlet fever	110	18
Cerebro-spinal meningitis	0	5
Measles	117	0
Diphtheria	255	50
Small-pox	18	1
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

Care of Milk as a Means of Preventing Disease.—The gravity of this matter calls for remedies which shall be effective and far reaching. The general measures of prevention we would suggest are the following: 1. The provision and establishment of a thorough and effective inspection of all dairies which contribute to the public milk-supply, for the purpose of discovering tuberculosis and

other infectious diseases among the dairy herds; of ascertaining the conditions under which the dairy cattle are cared for, fed, and milked; of discovering the existence of carelessness in obtaining the milk by dairymen, and the quality and location of the water-supply used by the cattle and used for cleaning and cooling the vessels in which the milk is received, kept, and transported; for the purpose, also, of ascertaining the existence or not of any infectious disease in the family of the dairyman, or of those in any way coming in contact with or handling the milk before it is shipped and during its transportation and delivery. 2. The absolute prohibition of the sale of milk from cattle found to be suffering from any infectious disease, or from dairies where there is liability of the infection of the milk through infectious diseases in the families of the dairyman or of his employees; the prohibition of the sale of milk which is at all altered in its normal chemical constitution; the absolute prohibition of the sale of milk from dairies where "distillery swill" or "brewers' grains" are fed to cattle. 3. The habitual employment of "tuberculin" by inspectors of dairies for the purpose of diagnosing the existence of tuberculosis in cattle, and the prompt exclusion from the dairy herd of tuberculous cattle; the punishment for the wilful violation on the part of the dairymen of the restrictions concerning tuberculosis, including the sale of milk from tuberculous cattle, by such heavy fines, coupled with imprisonment, as would effectively remove the danger to the public health. 4. The establishment of a high legal standard of purity nearly approaching the standard of pure average milk as it comes from properly cared for and properly fed cows. There should be a standard also for skimmed milk, which is sold as such, of a sufficiently high grade to exclude absolutely the sale of "separator slop." 5. The inspection of dairy milk at the dairy, in transit to the shipping station, or at the shipping platform. Dairy milk should be required to reach the standard fixed and applied in the city where it is consumed, and under similar penalties. The watering or adulteration of milk by the dairyman or his employees should be punished by heavy fines, coupled with imprisonment. Rigid inspection of the milk while it is in possession of the city dealer, and of his method of handling and trafficking. The city inspection should also embrace groceries, drug shops, and hotels, etc., where milk is retailed to the public. 6. The prohibition of the sale or transportation of milk by the dairyman, whenever either the milk or condition of the cattle, their surroundings in the stables, or the method of obtaining and handling the milk, have been condemned by the dairy inspectors as liable to be unwholesome or infectious. 7. A monthly publication of the names and places of business of all persons who have been found to have in their possession or selling unlawful milk, in order that the consumers may be warned of their danger, and in order to cause a discontinuance of fraudulent practices where they exist, or to correct inexcusable negligence on the part of dealers who may violate the law through ignorance. 8. A requirement that vendors of milk shall be prosecuted each time they are found to have in their possession or to have sold or offered for sale unlawful milk, whether they have personal knowledge thereof or not, and the establishment of such heavy fines, coupled in the case of repetition of the offence with imprisonment, as will render the handling and sale of such milk unprofitable to the vendor. 9 No milk should be allowed to be sold in any city except by those having a license under authority of the local board of health, and this provision should apply to the regular milk-dealers, groceries, and other shops where milk is sold, drug-stores, and other places where milk comprises a part or the whole of beverages sold to the general public. No vehicles should be permitted to be used in the distribution of milk to customers, or in the transportation of milk within the city limits, except those duly licensed under the same authority. The sale or shipment of milk by dairymen should be prohibited unless they are licensed. These licenses should be good for one year only, and should be forfeited by a violation of the law regulating the shipment, treatment, or sale of milk. The establishment of this system of licensing dairymen and vendors of milk should accomplish the double purpose of rigid supervision and the raising of sufficient funds to meet the expenses of inspection and of prosecution for violation of law; and the license fees should be so assessed as to amply meet the requirements. 10. The consumer should exercise scrupulous care in the handling of milk in the dwelling. Vessels containing it should be absolutely clean and well scalded. The milk should be kept cool and protected from the air and dust as well as from all kinds of exhalations. None should be accepted from the vendor which is perceptibly acid. When the milk is intended as food for infants, unusual care should be exercised by the housewife that an excellent quality of perfectly fresh, cool milk is delivered. If milk in the slightest degree objectionable is served by the vendor, send a sample of it at once to the local health authorities for examination, and call upon them to correct the abuse. The intervention of the latter will do infinitely more good in permanently remedying the trouble than individual protests by a customer to the vendor can possibly do, and at the same time will benefit his neighbors as well as himself. Aid the health authorities in every possible manner to oblige the vendors of milk to live up to the law and respect the rights of the public. The milk intended for babes should not be kept in one general receptacle, but immediately upon entering the house should be distributed in a number of six- or eight-ounce bottles which have been perfectly cleansed and sterilized beforehand. The bottles should be at once well stoppered, either with cork or washed surgical cotton, and placed in an ice box and maintained there till used. In summer it would be better, before placing in the ice box, to heat the milk in the bottles to 160° F. for fifteen or twenty minutes, in order to kill, or at least inhibit, the bacteria which the milk may contain. This can be conveniently done by placing the filled bottles in a deep saucepan containing warm water as high as the neck of the bottles, and then placing the pan on a hot stove for a half hour. The bottles should then be taken out of the pan and set aside in a cool place for a few minutes before placing in the ice box. When it is time to feed the baby, remove one bottle from the ice-box, warm it, remove the stopper, place a perfectly clean sterilized rubber nipple over the mouth of the bottle. Avoid rubber tubes and complicated nipples, which are always difficult, if not indeed quite impossible, to keep perfectly clean and free from microbes in warm weather. Never make the mistake of using the same bottleful for two separate feedings; throw the remains away By such simple procedures, costing little trouble, the life and good health of many a bottle fed infant can be saved, even in the hottest weather and most unhealthy surroundings.

The first nine of the foregoing suggestions should form the basis of laws regulating the sale of milk, and they should be vigorously executed without leniency or favoritism. With enactment and thorough enforcement of such laws the "slaughter of the innocents," which we now have so much reason to bewail, would practically cease, and immense annual gains in the economic wealth of the nation would certainly follow the great saving of life. Meanwhile, in the absence of such laws the mothers can do much to save the lives of their little ones in the manner pointed out.—*The Dietetic and Hygienic Gazette.*

Gall-stones.—Dr. T. H. Buckler treats gall stones with chloroform and succinate of iron (*The Medical Age*, April 10, 1894). If anyone contemplates an operation for gall-stones, he says, let him first try the more quiet and less obtrusive method of dissolving it, and depend upon it, there will be no necessity for a resort to the knife.

The University of Dorpat, which is now officially known as Tvryeff, is rapidly being Russianized. The official language is now Russian, and as rapidly as vacancies occur in the professional staff the places of the Germans are filled by Russians.

Parson, must the, pay? 496, 642.
Parsons, J. Inglis, notice of book by, 501.
Pasteur Institute, protest against a, 446; report of the, 679.
Patella, fracture of the, 233, 247; rupture of the ligament of the, 637.
Patent medicines, the sale of, 818.
Pathological processes, vital adaptability to, 432.
Pathological Society of London, 150, 213, 310, 407; of New York, 23, 118, 411, 536, 672
Payn, Dr. Frederick G., death of, 306.
Peabody, C. A., Hale's lifting column, 710.
Peddie, William, notice of book by, 603.
Pediculi pubis, lotion for, 26.
Peet, Walter B., some notes on aural development in a case of congenital deafness, 789.
Peliosis rheumatica, 773.
Pelvic abscesses, instrument for evacuating and draining, 21.
Pelvic organs, imperfect, in well-developed women, 87; conservative surgery of the female, 733.
Pelvic surgery, 214.
Pemphigus treated by the sulpho carbolates, 821.
Penis, horny growth of the, 223.
Pennsylvania State Board of Medical Examiners, 147.
Pension office, ex-Confederates and the, 244, 381.
Pepper, William, notice of book by, 436; resignation of, as provost of the University of Pennsylvania, 529.
Percussion hammer, a neurological, 772.
Pericarditis, fibrinous, treatment of, 502.
Pericardium, wounds of the, 638.
Perineal operations, jacket support of the legs in, 190.
Perineum, new and short method of closing the, 492; new apparatus for use in operating on the, 63; rupture of, caused by the axis-traction forceps and antepartum douche, 680.
Periostitis, acute, 28; the liquid of albuminous, 246.
Peritoneal cavity, diagnosis of small effusions in the, 106.
Peritoneum as a suture medium, 638.
Peritonitis, bacteria of, 646; puerperal, 219; treatment of, 407; treatment of postoperative, 278; tubercular, 798; tubercular, non exudative, 149; tubercular, treatment of, 473
Perivaginitis simplex, 58, 391.
Permanganate of potassium as an antidote to certain poisons, 243; as an antidote to morphine, 200, 316, 442, 459, 460, 642.
Pernet, George, the armamentarium of a Gallo-Roman surgeon of the third century, 695.
Pessary in the dilated cervical canal of an old woman, 347.
Pfarre, Dr. Philip H., death of, 757.
Pharmacopœia, the changes in the, 447.
Pharmacy, chemistry in its relation to, 435.
Pharyngitis, follicular treatment of, 117.
Pharyngo mycosis, 12.
Philadelphia County Medical Society and the American Medical Association, 636.
Philadelphia, Municipal Hospital of, 19.
Phimosis, 26.
Phlebitis following pneumonia, 525.
Phlegmon, gas, 15.
Phonograph, otitis communicated by the, 398.
Phorometer, adaptation of the Maddox cylinder for use on the, 678.
Phosphate of soda in tabes, 122.
Phosphorus, biological importance of, in its organic combinations, 435.
Photography, abuse of, in medicine, 752.
Phrenic nerve, compression of the, in glottic spasm, 398.
Phthisin crystals, 725.
Phthisis, acute, 213; dietetic treatment of, 353; endowment for laboratory research in the therapeutics of, 51; experimental, in rabbits, effects of tuberculin in, 802; fever of, in relation to prognosis, 141; inhalation of carbolic acid in, 407; inalations of mint in, 50, 340; night sweats in, 317; pneumatic cabinet in, 512; systematic exercise in the prevention of, 763; tachycardia in, 814.
Physician, a, found guilty of murder, 174; an eccentric, 339; effects of medical life upon the, 350; medical treatment of the, by the, 145; testimony of the, regarding his patient, 176; the, of sacred history, 182; the wife of the, 337.
Physicians and the income tax, 174; licensed, in Massachusetts, 700; the number of American, 276; taxing, 819.
Physicians' Mutual Aid Association of New York, 446.
Physiology, debt of, to medicine, 791.
Picric acid for burns, 807.
Piersol, George A., notice of book by, 373.
Pierson, Samuel, fracture of the head of the fibula by muscular action, 367.
Piffard, Henry G., a simple means of increasing the aperture and improving the performance of some immersion lenses, 362; the Babcock test as a means of determining the commercial and nutritive value of milk (bovine and human), 46.
Pilcher, James E., notice of book by, 501.
Pilocarpine in disease of middle ear and labyrinth, 409.
Piperazine, 60.
Pittsburgh, a dirty city, 529.
Pityriasis versicolor, cure of, 26
Pizarro, a congenital criminal, 446.
Plague, the Chinese, 819.
Plaster cast, horizontal position for applying, 318.
Playfair, W. S., notice of book by, 245.
Pleasant Plains, N. Y., the salubrity of, 352, 429.
Pleura, extensive adhesions of the, 205.
Pleurisy and malaria, confusion of the fevers of, 535; caused by the pneumococcus, 407, 413; fibrinous, treatment of, 502; hemorrhagic, 177; provisional costotomy for acute exudative, 570; treatment of serous and purulent exudative, 570.
Pleuritic exudation, to prevent extension of, 317.
Pleurotomy, 569.
Pneumococcus of Friedlander, innocuousness of, in the rabbit, 246.
Pneumonectomy, 94.
Pneumonia, acute catarrhal, importance of early diagnosis and prompt treatment in, 798; and aphasia, 149; chloride of calcium in, 144; disappearance of gonorrhœal discharge during, 81, 269; influence of atmospheric pressure on the prevalence of, 798; of the apex, 502; pathogeny of, 383; phlebitis following, 525; treatment of, 789, 797; treatment of certain symptoms of, 700; treatment of lobar, without opium or digitalis, 139
Poisoning by lead, monosulphite of sodium in the treatment of, 696; by morphine, permanganate of potassium as an antidote for, 200, 316, 442, 459, 460, 642; by ptomaïne in turkey, 14, 155, 380; by quinine, 138; by rhus toxicodendron, fatal, 727; by salicylate of soda, 149; by sterilized meat and milk of tuberculous animals, 292; by vetches, 535.
Poliomyelitis, acute anterior, 341.
Poliorromenitis, subacute, 534.
Politics in medicine, 82.
Politzer, notice of book by, 501
Post-Graduate Medical School, the new, 595.
Pott's disease of the spine, 344.
Poverty and disease as studies in sociology, 305.
Powers, Charles A., further observations on the physiological occurrence of conical stump after amputations in children, 423.
Practitioners' Society of New York, 21, 152, 342, 803.
Pregnancy, after removal of one ovary and part of the other, 81; albuminuria in, 154, 814; and Bright's disease, 247; diagnostic aids in, 705; extra uterine, rupture, laparotomy, recovery, 303; fatal nausea and vomiting of, 769; mistaken for a cyst, 408; pruritus during, 376; simultaneous intra and extra uterine, 631; tubal, 571.
Pregnant women, methodical examination of, in private practice, 224
Prescriptions, indiscriminate use of, 646; the ownership of the, 399.
Prevention of disease, 248.
Priapism, an epidemic of, 170.
Price, A. F., the treatment of syphilis with sulphate of copper, 129.
Prize, Boylston, award of the, 795; of the Medical Society of the County of New York, 370; of the Spanish Academy of Medicine, 711; Riberi, award of the, 275; the Merritt H. Cash, 467.
Professional men, incomes of, 173; tax on incomes of, 210.
"Professor of wind and water," and his misleading statements, 255.

Prostate, castration for hypertrophy of the, 761, 794; enlarged, 26; enlarged, boutonnière operation for, 23; removal of adeno-myoma from the, 761.
Prostitute, registration of the male, 445.
Prostitution, relation of the medical profession to the abolition of, 480; the control of, 369, 377.
Proteids, general nature of, 449.
Proteolysis, digestive, 417, 449, 481, 513, 545, 577.
Pruritus, during pregnancy and the puerperium, 376; hiemalis, lotion for, 283; icteric, 472; lotion for, 26; vulvæ from jealousy, 563.
Psoriasis, ointment for, 543; treatment of, 568
Psychology, some less cultivated phases of, 390.
Ptomaines in fish, 314; poisoning from, after eating turkey, 14, 155, 380.
Public health and the State, 431; bill to establish a department of, 175; veto of bill amending the law on, 695
Puerperal eclampsia, bacillus of, 742.
Puerperal insanity, 17.
Puerperal period, pruritus during the, 376.
Puerperal sepsis, 219; endemic of, in Auvergne, 246.
Puerperal state, ovariotomy in the, 341.
Pulse, hepatic, 471.
Purpura hæmorrhagica, 473; sulpho-carbolates in, 821; the blood in, 111.
Pyæmia complicating typhoid fever, 525.
Pyelonephritis, bacteriology of, 732.
Pyle, J. S., opening the cranial cavity with a new set of instruments, 163.
Pyloroplasty, a successful case of, 135.
Pylorus, stenosis of the, 247.
Pyothorax and its treatment, 622, 709, 744.

Q

Quacks, a bill to license, 466; a poetical correspondence on, 744.
Quarantine, national, the bill concerning, 48, 304.
Quinine, poisoning by, 138.
Quintuplets, 307, 370.

R

Rabies in cows, epidemic of, 757; nervous lesions in, 560.
Rachitis, and infantile convulsions, 566; discussion on, 769.
Radii, congenital absence of both, 463.
Rafter, George W., notice of book by, 436.
Railroad hospitals, new, 818.
Railway coaches, disease in, 695, 808.
Ranney, Ambrose L., the eye treatment of chorea, 551, 582; the eye-treatment of epilepsy, 476.
Ransan, Dr. A. A., death of, 338.
Rattlesnake venom, action of, upon the bactericidal power of the blood-serum, 663.
Rauch, Dr. John H., death of, 403.
Raymond, James Harvey, guaiacol as a topical application in the treatment of acute tonsillitis, 364.

Raynaud's disease, 701.
Recruit, selection and physical examination of the, 329. 355.
Rector, Joseph M., an experiment with permanganate of potassium as an antidote for morphine poisoning, 460.
Rectum, excision of the, 25; incontinence of the, and its cure by torsion, 161; prolapse of the, new operation for, 216; supra sphincteric ulcers of the, 94.
Red Cross, protection for the, 498.
Red glass and blue glass, 276.
Red light for small-pox, 310, 344.
Reflexes, localization of the, 566.
Reich, A., diabetic multiple peripheral neuritis, 59.
Reichard, E. E., the treatment of lobar pneumonia without opium or digitalis, 139.
Rest, in chlorosis and heart disease, 142; in typhoid fever, 705.
Retina, detachment of the, 766; rupture of lymph-sheath of a vein in the, 768.
Rheumatism, gonorrhœal, 473; local application for, 60; treatment of acute, 473; treatment of chronic, 336.
Rhinitis, atrophic, application for, 317.
Rhode Island anti-vaccination bill, 531.
Riberi prize, award of the, 275.
Ribs, desternalization of the, 207.
Ricketts, B. Merrill, exstrophy of the bladder, 458.
Rivinius, foramen of, 741.
Robinson, A. R., notice of book by, 375.
Robinson, Beverley, the treatment of uræmia, 321, 342; the use of purgatives in the treatment of typhoid fever, 542.
Rockwell, A. D., the action of electricity on the pneumogastric—is it of value in chloroform narcosis? 236, 510.
Rocky Mountain region, the climate of, 300.

Rush College Laboratory, 18.
Russell, Dr. Dwight, death of, 403.
Russell, Louise, unique path of a revolver bullet, 269.
Russia, physicians in, 741.

S

Saccharine as an intestinal antiseptic, 704.
St. Louis, pen pictures in, 724.
St. Paul-Minneapolis, a healthy locality, 529.
Salicylate of soda, poisoning by, 149.
Salicylic acid, external use of, 64; local action of, in liniment, 137.
Salipyrin, 469.
Salts, neutral, influence of, on serum alexine, enzyme, toxalbumin, blood-corpuscles, and anthrax spores, 110.
Sanitary building, a unique, 133.
Sanitary conference, international, of Paris, 592.
Sanitary insurance, 384.
Sanitary motes and beams, 82.
Sarcoma, developing on adeno-fibroma, 410; endosteal of the radius, 283; of the ilium, inoperable, 599; of the tongue, 410; round celled, of the ovary, 237.
Sarsaparilla, 210, 314, 560.
Savage, G. C., notice of book by, 604.
Scarlatina, apparatus for subliming calomel in the treatment of, 644; local lesion of, 113, 115; membranous inflammation of the throat during, 213; pathogenesis of, 149.
Scars, unpigmented, tattooing, 743.
Schenck, S. L., notice of book by, 405.
Schiff, Professor Moritz, jubilee of, 274.
Schumpert, T. E., locomotor ataxia, with report of a case cured, 629.
Sciatica, pills for, 317.
Scopolaminine, 696; action of, on the eye, 216.
Scorbutic gingivitis, microbe of, 647.
Scorbutic pseudo-paralysis, 279.
Scrofula, iodoform in, 317; senile, 95.
Scurvy in children, 279, 770, 811, 820.
Sea air and mountain air, 511.
Searles, F. R., reckless use of chloral, 29.
Seeligmann, Gustav, an aseptic obstetrical instrumentarium, 382.
Seelye, H. H., atropia poisoning from eating turkey, 14; turkey and ptomaïne, 380.
Segur, Gideon C., notice of book by, 605.
Seitz, Carl, notice of book by, 532.
Semeleder, F., the canny Prince of Servia, 679.
Senn, N., notice of book by, 533.
Sepsis, puerperal, 219.
Septicæmia, gastro-intestinal, of infants, 527.
Septum-knife, annular, 189.
Serum-therapy of syphilis, 223.
Servetus, memorial function in honor of, 747.
Servia, the canny Prince of, 679.
Seward, W. M., a case of ectopic gestation—rupture at about one month—immediate laparotomy—recovery, 303.
Sewer-gas, effect of, in the production of disease, 698.
Sex, pre-natal determination of, 4.
Sexual debility in the male, physical and psychical causes of, 181.
Sexual instinct, effect of castration upon the, 173.
Sexual perverts, castration of, 479.
Shepherd, Francis J., a successful case of pyloroplasty, 135.
Shipps, William H., compound comminuted fracture of the skull, 237.
Shoulder, amputation at the, control of hemorrhage in, 703; neuropathic inflammation of the, 409.
Shrady, George F., some points in the diagnosis of appendicitis, 1, 21.
Sickness, sneezing in, 121, 480.
Sigmoid flexure, rupture of the, 310.
Simon, Charles E., a case of acute gastro-enteritis due to mustard, 346.
Simpson, Robert, notice of book by, 309.
Singultus, obstinate, 367.
Sinnett, Dr. J. H., resolutions on the death of, 467.
Sinus, frontal, suppuration of, 396; lateral, thrombosis of the, 741.
Size and quality, 84.
Skin, cold as an etiological factor in diseases of the, 764; thyroid extract in diseases of the, 247, 248, 763; tuberculosis of the, new treatment for, 272.
Skin-diseases, some cases of, at Mr. Hutchinson's clinical museum, 94.
Skin grafting, 254.
Skin-transplantation, Thiersch's method of, 512.
Skull, compound comminuted fracture of the, 237; fracture of, 526; treatment of depressions in the, in the new-born, 166; trephining for fracture of the, 246.
Sleep, chloroforming in, 402.
Sleeping-room, proper care of the, 425.
Sleeplessness, natural remedy for, 199.
Sloan, T. W., the horizontal position for applying plaster cast, 318.
Small-pox, and antiseptic vaccination, 465; in the city hospital, 112; light on the question of, 114; red light for, 310, 344; postal transmission of, 712; spread of, around hospitals, 252; the goddess of, 711; treatment of, 469.
